ALTHOUGH THE PURELY MECHANICAL NATURE of cardiac pumping is taken for granted by modern scientists, this view has not always been accepted in the past. Only during the last hundred years were the forces of muscle contraction finally stripped of the 'vis vitalis' and ascribed exclusively to energy transformation according to the laws of physics and chemistry. In this historical process, the heart which had been formerly thought of as the seat of emotions, was deprived of all metaphysical connotations and became an organ of purely mechanical function just

as the skeletal muscle. It is of interest to trace briefly the emergence of this concept (160, 161).

During the age of the pyramids (3000–2500 B.C.) an unknown Egyptian clearly recognized the heart as the center of a system of distributing vessels and associated the pulse with the cardiac beat. The Greek philosopher Alcmaeon of Croton (about 500 B.C.) distinguished the veins from the arteries and asserted that the seat of sensation was not in the heart but in the brain. The function of the heart as a pump was apparently expressed for the first time by Plato (427–347 B.C.) when he stated: it "pumps particles as from a fountain into the channels of the veins, and makes the stream of the veins flow through the body as through a conduit." Hippocrates (493–423 B.C.) had described the cardiac valves, the ventricles and the great vessels, but he did not refer to the pumping action, which he might have taken for granted. For Aristotle (384–322 B.C.) the heart was the seat of "innate heat" and also of the soul. This notion was probably based on the observation that death results from dissection of the beating heart. However, from his studies on the embryonic chick heart Aristotle may have had knowledge of the pumping function. Erasistratus (310–250 B.C.), who described the aortic valves, pulmonary valves, and chordae tendinae, and Galen of Pergamon (131–201 A.D.) both stated that the heart is a pressure-suction pump. Their view was founded mainly on the assumption that during diastole blood was sucked into the ventricles by active enlargement of the cardiac walls [discussed by Ebstein (40), Böhme (14)]. They also believed that blood is expelled backward into the caval veins during ventricular systole. The first definite statement concerning the continued forward flow of blood from the right ventricle through the lungs into the left heart was made by Ibn an-Nafis (1210–1299 A.D.). The first scientist of the Renais-

¹ The results of some recent experiments of the authors and their colleagues are quoted in this paper. This work was supported in part by USPHS grant H-3796, and grants from the Life Insurance Medical Research Fund and the Georgia Heart Association.

sance who recognized the heart as a hollow muscle and probably as a pump was the artist-engineer, Leonardo da Vinci (1452–1519 A.D.), who stated: “The heart is a principal muscle, in respect of force, and it is much more powerful than the other muscles” [Keele (90)]. However, it remained to William Harvey (1578–1657) to prove that the heart, and not the liver, is the center of the vascular system and that it propels the blood unidirectionally by its rhythmical contractions as would the repeated strokes of a man-made pump. The microscopic proof of the muscular nature of the heart was brought by Niels Stenson (1638–1686), who demonstrated that the substance of the heart is composed of fibers, membranes, arteries, veins, and nerves just as is the substance of other muscles. Once this important point had been firmly established, it became customary to consider the heart as a pump, to develop analogies with mechanical systems of fluid transfer, and to apply to the myocardium the increasing knowledge about skeletal muscle contraction. The present chapter is a rather general and classically oriented treatment of the mechanical function of the heart. It attempts to provide an understanding of the anatomical structures, while avoiding teleological oversimplification as well as useless controversies about functions.

The role of the heart consists of providing the body tissues with a continuous stream of blood. The heart fulfills this function by converting potential energy (primarily chemical energy, secondarily energy of position) into kinetic energy, as movement is imparted to the blood ejected from the ventricular cavities. From the standpoint of cellular function at large, it does not matter whether tissue perfusion is brought about by alternate contraction and relaxation of myocardial cells, or by the action of an artificial pump. This concept has been established on a firm experimental basis by the advent of extracorporeal circulation techniques, whereby a mechanical pump substituted for the human heart can fully support the circulation. Thus the heart can be looked upon as a pump inserted in the circulatory system and its function can be described by analogy with purely mechanical systems.

Mechanical pumps are divided into two main classes: kinetic pumps and positive displacement pumps. In the former class, kinetic energy is added to the fluid by the forced rotation of an impeller (fig. 1A). In the latter class, the fluid is progressively displaced from a suction inlet to a discharge opening. Two kinds of positive displacement pumps need to

FIG. 1. Mechanical analogues for some pumping principles embodied in the heart. A: kinetic pump in which energy is added to the fluid by the rotation of an impeller. B: rotary pump in which fluid is propelled through squeezing a resilient tube by means of rollers mounted on a rotating arm. C: reciprocating pump in which fluid is displaced by the back and forth movement of a diaphragm while valves give direction to the stream.

be mentioned here. In rotary pumps (fig. 1B), moving members trap a portion of the fluid in a chamber of pliable tubing and conduct it toward the outlet. The segment of tubing occluded acts as a valve to prevent backflow. In reciprocating pumps (fig. 1C) a cavity limited by two valves is subjected to the action of a piston or diaphragm. As the piston moves back and forth, fluid is drawn in through the suction valve and forced out through the discharge valve.

The action of the heart in some invertebrates can be compared to that of rotary pumps, since forward movement of fluid is obtained by peristaltic movements of the walls. In the mammalian heart also some degree of blood propulsion may be accomplished on the “progressive cavity principle” as in rotary pumps, particularly the displacement caused by the wringing action of the ventricles. However, cardiac action in vertebrates most closely resembles that of reciprocating pumps. It is characterized by pulsatile action, by the presence of valves, and by the capability of the pump to be adjusted in terms of either speed, or volume displacement, or of speed and volume displacement simultaneously. Although the design of the heart has nothing in common with that of kinetic (centrifugal) pumps, its control displays two characteristics for which kinetic pumps are appreciated in technology: namely that the volume

output is directly related to the input pressure, and is inversely related to the pressure head against which the pump works. Like centrifugal pumps, the heart has the tendency to deliver a higher flow as more blood is fed into it at the atrial level; it also provides a lower flow when the resistance to ejection in the vascular system increases.

A close look at mechanical pumps for cardiac substitution throws a light on built-in features of the natural heart that one easily takes for granted. Adequate perfusion of an adult human organism under all possible conditions requires that:

- 1) The heart be able to move blood volumes ranging from 3 to 30 liters per min and to pump against pressures up to 300 mm Hg.
- 2) Even at maximal cardiac output, the flow velocity must not exceed the limit of tolerance for mechanical trauma to blood corpuscles through turbulence, friction, or cavitation (1-2 m/sec).
- 3) The relationship between stroke volume and stroke rate must not deviate much from an optimum which is set by the elastic properties of the cardiac walls, the time needed for efficient transformation of potential into kinetic energy and by the lowest flow velocity compatible with the output required.
- 4) The valves must easily open during their flow phase, yet be competent and prevent regurgitation of blood during their holding period.
- 5) The regulation of the pumping action must be automatically controlled through sensing elements with feedback mechanisms which adapt the output to the tissue demands [see also Wagner (153)]. These control mechanisms must integrate hemodynamic data (e.g., perfusion flow, arterial and venous pressures) and metabolic data (e.g., arteriovenous oxygen difference) to maintain viable conditions.

Considering these points in more detail, one must first emphasize the pumping capacity of the heart. As 3 to 30 liters per min of blood is pumped by the left ventricle into the systemic circulation, practically the same amount is ejected by the right ventricle into the pulmonary vascular bed. Furthermore, the atria have some pumping function of their own, so that the combined pumping of all the chambers of the human heart is in the order of 7 to 70 liters per min, depending upon the state of muscular activity. A range of this magnitude (1:10) is not easily obtained in artificial pumps and, when it is reached, it is at the price of considerable sacrifices in mechanical efficiency (ratio of work produced to fuel consumed). On the contrary, the mechanical efficiency of the heart does not seem to be very closely related to cardiac output.

The extended scale of activity over which the heart can perform is certainly facilitated by the elastoviscous properties of the cardiac walls. The cavities are distensible over a wide range of volume increments without much increase in intraventricular or intra-atrial pressures [see fig. 2, and Little (99)]. Therefore the heart can easily accommodate and deliver varying stroke volumes even if the stroke frequency remains unchanged. Furthermore the time needed for the transformation of chemical into mechanical energy apparently comprises only a fraction of the systole. At a constant stroke volume the heart can increase its minute output simply by beating faster and shortening the pause between the strokes without affecting the energy conversion processes. The limiting factor of cardiac output at high heart rates is not an encroachment on the time needed for energy conversion but an encroachment on the time needed for filling the pump chambers (ventricular filling phase).

Another fundamental difference between artificial pumps and the heart is that in the former a force is applied from the outside to activate a part or the entire wall of the pump chamber, whereas in the latter the force is developed within the wall of the pump chamber itself by small elements, the muscle fibrils, which alternately shorten and lengthen. Furthermore, since the heart is surrounded by other resilient structures in the thorax, there is an interaction of the physical forces developed in the myocardium and those developed either passively or actively in these structures [Pfuhl (129, 130), Blair & Wedd (12)]. For example, during ventricular contraction and ejection the elastic forces of the lungs oppose to a small extent the diminution of the ventricular size, whereas during ventricular relaxation the same forces of the lungs enhance slightly the expansion of the ventricles. These forces are said to be negligible as compared with the intravenous filling pressures (60, 64). Mechanical effects are exerted upon the rhythmical form changes of the heart by such structures as the pericardium, the attachments of the heart to the large vessels, the sternum, the mediastinal tissues, and the diaphragm through its changes in position during respiration or because of varying degrees of abdominal filling. The complexity of these forces, in terms of direction and magnitude, and their continuous changes during the cardiac and the respiratory cycle make it presently impossible to evaluate quantitatively the contribution of extracardiac structures to cardiac pumping. Nevertheless, their importance is demonstrated by the possibility of pumping blood solely by the action

of external forces on the heart [Hosler (81), Stephenson (150)]. In closed-chest cardiac massage, vigorous pressure on the lower part of the sternum causes ejection of the ventricular content into the large arteries. Conversely, when pressure is released, the recoil is sufficient to permit the venous pressure to fill the ventricles again [Kouwenhoven *et al.* (92)]. In this manner, a sufficient, though subnormal, cardiac output can be maintained in the absence of any myocardial activity. This points again to the fact that, in principle, it does not matter whether the propulsion of blood through the body is brought about by the contraction of cardiac fibers or by any other suitable forces applied to the blood contained in the ventricles.

MACROSCOPIC STRUCTURES

A great deal of commonly accepted knowledge about cardiac pumping is derived from purely morphological considerations. Although conclusions reached in this manner have occasionally proved to be correct, morphological reasoning often leads to fallacious functional interpretations of structural findings. In the case of the heart, physical vector analysis of all the mechanical forces involved is especially difficult because of the great complexity of the anatomical structures and of the perplexing geometry of cardiac filling and emptying. We have only a limited knowledge of the sequence of events as they occur during muscular contraction and relaxation within various parts of the myocardium. In this particular section an attempt is made to describe the macroscopic structures of the heart with reference to their probable function as deduced from the anatomical observations. A topographic anatomical description of the heart is available in standard texts (51, 95, 98, 101).

Composition of Cardiac Tissues

The myocardium is the most important structure of the heart because its contraction causes the blood to flow. However, it should be realized that only part of the cardiac walls consists of muscle fibers, and that within the muscle fibers, the contractile substance is limited to the fibrils. Indeed about half of the heart's weight is made of noncontractile material such as the sarcolemma in the muscle fibers, connective tissue in the heart skeleton, tendons and valves, and finally blood vessels, lymphatics, and nerve fibers. All these elements are interwoven with

the muscle fibers or closely connected to them (45, 59). During cardiac contraction or relaxation, they are deformed and resist to some degree the shortening or lengthening of the myofibrils.

Little is known about the mechanical effects of the coronary vessels upon the function of the ventricles. Though relatively inconspicuous in a "dead" heart, they appear heavily engorged with blood in the live organ. In fact, since 5 to 10 per cent of the cardiac output passes through the coronary system, a significant mass of the beating heart consists of circulating blood contained within the anatomical bounds of the epicardium. During heavy exercise the coronary blood supply is probably so great that one might look upon the myocardium as a spongy structure of muscle fibers suspended like chains of islands in a lake of blood. In the past it has been postulated frequently that the degree of filling of the coronary vascular bed affects in some form the ventricular contraction.

FIG. 2. Left ventricular pressure-volumes curves of a dog heart illustrating the changes resulting from coronary perfusion. The freshly excised heart of a 13.5-kg dog was submerged in Locke's solution and assumed its elastic equilibrium state (zero transmural pressure, origin of the coordinates) upon cessation of spontaneous contraction. The curves were obtained by addition or reduction of the intraventricular volume [Brecher & Kissen (22)]. The origins of the coordinates for the perfused and unperfused heart were arbitrarily superimposed. At negative (and up to +5 mm Hg) intraventricular pressures the ventricle accommodated a greater volume with coronary perfusion than without. At pressures above +5 mm Hg the ventricle accommodated less fluid with coronary perfusion than without (Horres *et al.*, unpublished data).

Most of these postulates were of speculative nature. For example, Donders (39) stated that "the blood which enters at the end of systole into the coronary arteries seems to cause a slight active expansion of the heart, especially of the ventricles." This view was originally formulated in 1855 by Brücke (26) and also advocated by Luciani (102). Based on X-ray kymograph studies, a modern modification of the same hypothesis was presented by Cignolini (34) without conclusive evidence. However, recent work by Salisbury *et al.* (141) indicates that the filling of the coronary bed affects the ventricular distensibility. There are indeed significant differences in the ventricular pressure volume relationship depending upon whether the coronaries are perfused or not [Brecher *et al.* (24)]. In figure 2 the S-shaped pressure volume curve of the ventricle with an empty coronary bed (solid line) is different from that obtained during coronary perfusion (broken line). This shift of the curve when the coronary bed is perfused indicates that the perfused heart accommodates more fluid at low intraventricular pressures and less fluid at high intraventricular pressures. Around the elastic equilibrium state (zero transmural pressure) the perfused heart is somewhat stiffer than the nonperfused heart. The effect of varying degrees of engorgement of the coronary bed upon the distensibility of the beating ventricle during the different phases of the cardiac cycle is still unknown.

The heart skeleton, the chordae tendineae, and the cells of the Purkinje system are noncontractile, yet are functional components of the myocardium. The heart skeleton (fig. 3) is represented by four interconnected fibrous rings of dense connective tissue, which surround the orifices of the great vessels. The musculature of the ventricles and atria, the roots of the large vessels, and the heart valves are attached to this skeleton, which also anchors the tendinous endings of the ventricular muscle (see below). An important function of the cardiac skeleton is to provide a firm basis for the attachment of the cardiac valves. Another function, though less frequently mentioned, is to aid in keeping the orifices open during the phases of blood inflow and outflow. During ventricular activity, the orifices undergo changes in form which probably involve also the cardiac skeleton as indicated in the different outlines of the orifices during systole and diastole in figures 4, 5, and 6. By inserting a finger through the atrial appendage in the intact beating heart, one can easily verify that the atrioventricular valve rings become smaller during ventricular contraction and larger during relaxation. This observation, which has not been substantiated by precise measurements as yet, indicates that the fibrous tissues of the heart skeleton are passively deformed by myocardial contraction and thereby store energy which is released

FIG. 3. Anatomic components of the heart depicting the relation of the fibrous skeleton to the heart chambers and arterial roots. The trunks of the aorta and pulmonary artery as well as the atria are fastened to the cranial aspect of the four annuli fibrosi, whereas the ventricles are attached to the caudal aspect. [From Rushmer (139).]

FIG. 4. Base of the human ventricles seen from their cranial aspect after the atria have been removed. The shape of the ostial orifices in the state of contraction differs significantly from the shape in the state of relaxation, as indicated by the dashed lines. [From Spalteholz (148).]

by elastic rebound at the beginning of muscular relaxation.

Many strands of myocardial fibers end with tendinous tissues. Yet one cannot compare them with skeletal muscle, since there is no bone to provide a fixed attachment. In reality, all myocardial fibers end on other myocardial fibers either directly or by insertion of connective tissue. For instance the myocardial fibers of the papillary muscles continue as chordae tendineae, which in turn lead via the bicuspid and tricuspid valve leaflets and the fibrous tissue of the heart skeleton to other myocardial fibers. This arrangement forms a circle of myocardial tissue, although with inclusion of a tendinous segment. Other myocardial fibers, such as many strands in the left ventricular deep bulbospiral bundles, simply form a circle. Since, in the final analysis, all myocardial fibers pull directly or indirectly on other myocardial fibers, the concerted effect of their contraction diminishes each heart cavity more or less concentrically [see also Hawthorne (67)]. It also stands to

reason that all muscle "fiber-rings" which include a noncontractile segment exert during their contraction a pull on the noncontractile segment, storing in it potential energy for release during myocardial relaxation.

The cells of the conduction system have a special position as far as their participation in the contractile process is concerned. They are derived from muscle cells, but their primary function is the fast conduction of excitation. Yet they do contain a small number of myofibrils and therefore must be expected to participate in the over-all myocardial activity. Since nobody has measured their contractile force, it remains a matter of conjecture whether Purkinje cells contribute to any significant extent to the force of ventricular contraction. It may be that their contraction serves only the purpose of diminishing the shear forces which would develop between myocardial and Purkinje cells if the latter remain purely passive. In the longitudinal direction the Purkinje cells are joined to intermediate cells which connect them to myocardial

FIG. 5. Superficial muscle layers of the maximally contracted human heart, viewed from the caudal aspect after separation of the atria (above) from the ventricles (below). The ostia of the contracted ventricles can be compared with their state in the relaxed ventricles (dashed lines). The changes in ventricular configuration during relaxation are also indicated by dashed lines. [From Spalteholz (148).]

cells. These intermediate cells contain an increasingly larger number of myofibrils as they approach the true myocardial cells. Merely judging from morphological evidence, they must contribute to some extent to the over-all contractile process.

Architecture of the Ventricular Myocardium

Since the ventricles perform more pumping action than the atria, the architecture of the ventricular myocardium has attracted most of the attention of functionally oriented anatomists. Despite extensive description by MacCallum (108), Mall (111), Mönckeberg (114), Benninghoff (10), Robb & Robb (136), Spalteholz (148), and Lev & Simkins

(97), much confusion still prevails. Opinions vary because it is difficult to dissect clearly the complexly arranged, intertwined and crisscrossing discrete muscle bands. Consequently, it is even harder to derive from the anatomic findings a picture of the direction of maximal pull of each muscular component, not to mention the concerted action of several components.

Many of the muscle bands encircle both left and right ventricles. According to the most commonly accepted terminology, one distinguishes four different muscles, the course of which can be best understood from semischematic drawings: the superficial bulbo-spiral (fig. 7), superior sinospiral (fig. 8), deep sinospiral (fig. 9), and deep bulbo-spiral muscle (fig. 10.)

FIG. 6. Superficial muscle layers of the maximally contracted human heart, seen from the ventrocranial aspect after separation of the atria (above) from the ventricles (below). The position changes of the great vessels and the ventricle outlines during relaxation are indicated by dashed lines. [From Spalteholz (148).]

According to Benninghoff (10), who uses a somewhat different classification, there are three interconnected systems which intersect rectangularly: *a*) the outer longitudinal fibers which connect to the outer contour fibers at the ostia; *b*) the ring fibers which encircle the entire chamber and curve around to form fibers of the ventricular septum; *c*) the internal longitudinal fibers which run from the contour fibers toward the apex (figs. 11 and 12). Benninghoff (10) analyzed the function of these various bundles on the basis of careful comparative anatomical studies and in vivo observations. He emphasized the concept that crossing of the fiber layers at right angles results in an over-all reduction of the cavity size, as first postulated by Carl Ludwig. Each of the three systems affects the entire heart and at the same time each of the ventric-

ular cavities. They act in such a manner that a reduction of the heart chambers does not occur equally in all directions but in such a manner and sequence that the cavities are emptied toward their outflow tracts. The evolution proceeded as follows: in lower vertebrates (fish, amphibia) there are no tendinous elements and all muscle bundles are ring shaped. In the mammalian heart secondary valves (atrioventricular) are formed from which the connective tissues of the fibrous rings of the atrioventricular valves and of the chordae tendineae originate and become inserted into the course of the ring-shaped muscle. The fibrous rings become connected to the roots of the arteries and form the solid trigona fibrosa, which furnish new insertions for many myocardial fibers (see fig. 4). In the evolutionary process the

FIG. 7. The superficial bulbospiral muscle as seen from the front of the human heart. *A* = Aorta; *M* = mitral orifice; *P* = pulmonary artery; *T* = tricuspid orifice; *AT* = anterior leaflet of tricuspid valve; *MT* = medial leaflet of tricuspid valve. A V-shaped section is cut from those fibers encircling the left ventricle subendocardially, so that the mitral valve may be seen. A similar band on the right is not sketched in. [From Robb & Robb (136).]

FIG. 8. The superior sinospiral muscle as seen from the anterior surface of the heart. Symbols as in fig. 7. Again the subendocardial layer has been cut through in order to show deeper structures. The window in the right ventricular wall shows the fibers from the trabeculated area running up to the anterior

and medial leaflets of the tricuspid valve. In both of these superficial muscles, blood vessels follow the muscle strands as they encircle the apex. [From Robb & Robb (136).]

FIG. 9. The deep sinospiral muscle as seen from the front. Note the division of the muscle at the posterior inter-ventricular sulcus, with fibers passing anteriorly to form most of the basal two-thirds of the septum; these septal fibers lie just distal to the band of the left head of origin at the base of the aorta. Symbols as in fig. 7. [From Robb & Robb (136).]

FIG. 10. The deep bulbospiral muscle, a powerful sphincter encircling the left ventricular base and enclosing both the aorta and the mitral orifice within its sweep. [From Robb & Robb (136).]

FIG. 11. Human ventricular myocardium after removal of the superficial muscle layers (seen from the caudal aspect). [From Spalteholz (148).]

spongiosa (spongy network of muscle fibers) is gradually reduced by the increasing compacta (solid tissue of muscle fibers). The phylogenetic remainders of the spongiosa are the muscular trabeculae, which are only moderately developed in the mammalian

heart and are almost completely replaced by compacta in the bird heart. In this respect the birds represent the highest functional development. According to Benninghoff (10) the spiral course of the muscle bundles toward the heart skeleton and the

FIG. 12. Course of the left ventricular muscle fibers. *Left*: preparation of human heart after partial removal of the superficial and medial muscle layers (seen from the dorsal aspect). *Right*: schematic presentation of the course of the muscle fibers as viewed from the dorsal aspect. [From Spalteholz (148).]

vortex formation near the apex are more pronounced in the mammalian than in reptile and bird hearts (see fig. 12, right).

Rushmer (139) points out that the division of the heart musculature into "sinospiral" or "bulbospiral" bundles is rather arbitrary and complicates the functional analysis. He suggests the division of the ventricular musculature into two groups of myocardial bundles, the spiral muscles and the deep constrictor muscles (fig. 13). He states in his unsurpassed description, the "functional anatomical analysis points to the direction physiological experimental work should pursue to verify... postulations and to obtain quantitative measurements."

Architecture of the Atrial Myocardium

The atria supply blood to the ventricles through three mechanisms: 1) passively, during the first part of their diastole, by serving as blood collecting chambers as long as the atrioventricular valves are closed by the high ventricular pressure; 2) still

passively, during the second part of their diastole, by serving as channels to permit the passage of blood from the systemic or pulmonary veins into the ventricles once the atrioventricular valves are opened; 3) actively, during atrial systole, by contracting and thereby pushing some blood into the ventricles shortly before the ventricular myocardium begins to contract. Since usually only a small fraction (10–30%) of the blood for ventricular filling is actively propelled by the atrial musculature and the resistance to inflow into the ventricular cavity is negligible, the normal atrial myocardium does not need to be thick walled.

The arrangement of the muscle fibers in the atria is much simpler than that in the ventricles. Two groups of fibers can be distinguished: 1) those which belong to one atrium only, and 2) those which are common to both atria (151).

Group 1: The fibers which lie in the wall of each atrium form muscle rings around the entrance orifices, i.e., the pulmonary veins in the left atrium and the coronary and caval veins in the right atrium. These annular fibers may act as sphincters, possibly

(A) ORIENTATION OF MYOCARDIAL FIBERS IN VENTRICULAR WALLS**(B) FUNCTIONAL COMPONENTS OF VENTRICULAR MUSCULATURE**

FIG. 13. Muscular structures of the ventricles diagrammatically arranged so as to reveal their functional components. *A*: blocks of tissue removed from the walls of the ventricles are composed of three layers of muscle. The myocardial fibers in these layers are oriented roughly in the three general directions indicated by the arrows. *B*: from a functional point of view, the ventricles are formed of two sets of myocardial bundles: *a*, the internal and external layers of spiral muscle, which enclose *b*, the ventricular constrictor muscles. The internal and external investments of the ventricular chambers are composed of the same muscle bundles, which are strongly twisted at the vortex and spiral in opposite directions from the apex toward the base. [From Rushmer (139).]

impeding, though not completely blocking, the backflow of blood into the veins during atrial systole. Looped fibers are also found which run from the anterior to the posterior segments of the atrioventricular junction, directly beneath the endocardium. At many places these fibers bulge into the atrial cavities forming various ridges which are most conspicuous at the inner walls of the atrial appendages, where they are named *musculi pectinati* from their resemblance to a comb.

Group 2: The fibers common to both atria are less numerous and lie superficially with respect to the proper fibers of each individual atrium. They consist of two thin muscle sheets which extend in a transverse direction from one atrium to the other. They can be subdivided into anterior and posterior fascicles. The muscle fibers of the atria and ventricles are separated

by connective tissue except at one place, known as the atrioventricular bundle or bundle of His.

The atrial cavity is surrounded by the thin myocardial fibers of both groups arranged in layers which are partly parallel and partly crisscrossed. The concerted action of all fibers is that, upon their contraction, they diminish the size of the atrial cavity and push blood into the region of least resistance, i.e., primarily into the ventricles, secondarily into the venous orifices. In addition to the main atrial cavity, there is an adjoining cavity formed by the lumen of the atrial appendage, also called "auricle" because of its resemblance to a little ear. The function of the auricles is unknown. Excision of the auricles in various operative procedures does not influence the circulation noticeably. Yet one cannot state bluntly that the atrial appendages have no function at all, since in a complex system, such as the heart, the function of a missing part may often be taken over or substituted by increased activity of other components. The mere presence of the atrial appendages results in an increase in the cardiac reserve. According to Benninghoff (10) and Böhme (14), the atrial appendages fill the space which is created within the pericardial sac during ventricular systole, as the ventricles eject blood into the large arteries and decrease in size. During this period the atrial appendages accommodate a considerable amount of blood. This blood is immediately available at the beginning of the rapid ventricular filling phase to be transferred into the ventricular cavities.

PRESSURE AND FLOW EVENTS DURING THE CARDIAC CYCLE

Historically the cardiac cycle was first divided into "systole," or period of contraction, and "diastole," or period of relaxation of the ventricles. It was soon recognized that the terms systole and diastole should refer equally to the atrial contraction and relaxation, although the ventricular events were most conspicuous in the gross observation of cardiac activity. Since the atrial contraction precedes that of the ventricle, terminological difficulties arose as to which systole was meant in describing the time sequence of cardiac events. As knowledge about the heart's action increased, it was also deemed necessary to subdivide the cardiac cycle in greater detail [see also Mackenzie (110)]. With the advent of methods for precise pressure recording from the cardiac chambers and great vessels, the ventricular pressure tracings

became the deciding guidelines for characterizing the phases of the cycle. The generally adopted subdivisions of Wiggers (156) stem from this era. Since other landmarks of cardiac activity such as flow, volume changes, or biochemical processes were difficult to record adequately, they were only correlated with the pressure curves at a later date.

It is still impossible to subdivide the cardiac cycle according to the most important physiological events: the blood flow into and out of the cavities. The approximate beginning and end of systolic ejection can be determined from simultaneous pressure tracings in a ventricle and in an arterial outflow tract. However, the precise timing of flow is only possible through direct recording of flow either at the root of the aorta or at the pulmonary artery [see also Moscovitz & Wilder (117)]. The recent advent of refined flowmeters will probably necessitate some adjustments in the original Wiggers scheme of the cardiac cycle. For the time being it is still preferable to retain the well-established scheme and to fit modifications into it, rather than to advocate a completely new one [see also Horowitz (80)].

Figure 14 [modified from Wiggers (156, 159)] illustrates in schematic form the sequence of pressure events during the cardiac cycle in the left ventricle, left atrium and aorta, and the volume changes in the combined ventricles [from Henderson (69)]. For time correlation, tracings of the heart sounds and of the electrocardiogram are added. This composite chart is mainly based on curves obtained in animal experiments.

The cycle is divided into two periods, systole and diastole. The former begins with the rise of ventricular pressure caused by ventricular contraction (fig. 14, 1) and ends at the onset of myocardial relaxation, 4, at the point when ejection actually ceases. This point then also represents the beginning of the diastole. The systolic period is subdivided into 1–2, isovolumetric ventricular contraction (50 msec); 2–3, maximum ventricular ejection (90 msec); and 3–4, reduced ventricular ejection (130 msec). The diastolic period is subdivided into 4–5, isovolumetric ventricular relaxation (120 msec), which includes a phase occurring just prior to the incisura and formerly called protodiastole (40 msec), plus the phase formerly known as isometric relaxation (80 msec); 5–6, rapid ventricular filling (110 msec); 6–7, slow ventricular filling or diastasis (190 msec); and 7–1, ventricular filling by atrial contraction (60 msec).

Numerous other cyclical events occur with each

FIG. 14. Scheme of the cardiac cycle. Time, totaling 1 sec, on upper margin. Numbers under lower margin indicate beginning and end of phases. Period of ventricular systole lasts from 1 to 4, period of ventricular diastole lasts from 4 to 1. Detailed description in text. [Figure (but not numbers in text) slightly modified from Wiggers (159).]

heart beat. They are correlated timewise with the phases of the pressure-volume cycle as follows.

1–2: *Isovolumetric ventricular contraction*. During this phase the myocardium builds up tension and this gives a fast rise of intraventricular pressure without change in the volume of blood contained in the ventricular cavity. The intraventricular pressure must rise to the level of the diastolic pressure prevailing in the aorta (or pulmonary artery) before blood can be ejected from the ventricles during the next two phases. The term “isovolumetric contraction” suggested by Rushmer (139) should supersede the older term “isometric contraction,” since at the beginning of this phase there is an actual shortening

of the fibers of the papillary muscles and trabeculae carneae which results in a tension of the chordae tendineae, and an approximation of the atrioventricular valves (139). Simultaneously, there is a passive stretching of the other still relaxed myocardial layers, mainly those of the outer walls of the heart [see also Hawthorne (67), Anzola (4), and Burton (29)]. The older term "isometric contraction" had the misleading implication that all myocardial fibers contract simultaneously and isometrically from the very start. Since in fact some muscle fibers shorten whereas others are passively lengthened during this phase, while the intraventricular volume remains constant, the term isovolumetric contraction provides a more accurate description than isometric contraction. Apparently instrumentation has not yet been refined sufficiently to decide whether or not there is in this phase a brief "latent relaxation" of cardiac muscle fibers as there exists in skeletal muscle fibers.

The shortening of the ventricle in the longitudinal axis results in a descent of the atrioventricular junction which in turn expands the atrial cavities. This leads to a precipitous lowering of the atrial pressure (fig. 14) which is often observed even before the ventricle ejects blood. The ventricular muscle fibers contract in a successive order, probably following the same time sequence as their depolarization (75, 142). As a consequence the blood contained in the ventricular cavity is pushed from the apex region toward the center of the ventricle and moves thereby closer to the outflow tract. The subsequent ejection from the ventricles can be looked upon as a continuation of the intraventricular movement of blood which already starts before the semilunar valves open. At the same time the ventricular cavity changes from a cylindrical to a more spherical shape, which from the energy standpoint represents a more economical way of discharging the ventricular content, once the aortic diastolic pressure is overcome. As pointed out by Rushmer (139), the asynchronous contraction of the ventricular myocardium readily explains the brief upward deflection at the beginning of isovolumetric contraction in the ventricular volume curve described by Wiggers (156) in fig. 14. This was formerly interpreted as an artifact in the recording.

Some arbitrariness is involved in determining accurately the start of isovolumetric contraction. In all pressure tracings the upward movement begins slowly in the form of a rounded curve. There is no abrupt beginning, inflection, or break. This becomes especially evident if one records the pressure events

by drawing out the time axis with fast moving paper as can be easily done today with electrical recording apparatus. The rounded beginning of the upward limb results from the combined effect of *a*) the contraction of the papillary muscles, and *b*) the simultaneous passive distention of some of the muscle fibers in the ventricular wall. Whenever the transfiguration of the ventricle causes a detectable rise of intraventricular pressure, then by convention the ventricular isometric contraction is said to begin. The fact that the different strands of myocardial fibers contract in sequence rather than simultaneously may also explain the great variability of the slopes of the pressure tracings in the early part of isovolumetric contraction.

The steepness of the slope during isovolumetric contraction is predominantly determined by the forcefulness of the fiber contraction. If the difference between the end-diastolic ventricular and end-diastolic aortic pressure remains unchanged, the duration of the ventricular isovolumetric contraction is shortened by sympathetic or sympathomimetic stimulation and lengthened by agents or conditions which depress the sympathetic control of the heart [Cotton & Maling (35), Gleason & Braunwald (54); see also Reeves *et al.* (133)]. Thus in forcefully contracting ventricles, the slope will be steeper than in feebly contracting preparations.

The atrioventricular valves close approximately at the beginning of isovolumetric contraction; the opening of the semilunar valves marks the end of this phase. The precise moment of the valve actuation is difficult to establish experimentally (discussed in the section on heart valves). In the interval between closure of the atrioventricular valves and opening of the aortic and pulmonary valves, the blood contained in the ventricular cavities is temporarily isolated from the fluid columns in the atria and arteries. However, the ventricular content does not remain still (10). In fact the blood which rushed into the ventricles at high velocity during diastole may aid in expanding the ventricular cavities. Since the inflow is primarily directed toward the apex, it is this part of ventricular wall which could be preferentially expanded. As the papillary muscles and trabeculae carneae begin to contract, the movement of the blood is deviated toward the outflow tract. This change in direction of flow is favored anatomically by the fact that the axis of the inflow tract and that of the outflow tract form an angle. In other words, the inflowing blood probably does not come to a complete standstill in order to reverse its direction of flow for ejection into the

arteries, but rather it keeps flowing in a curve from the main direction of the inflow tract toward the outflow tract. This translocation of blood within the ventricle during the isovolumetric phase is energy preserving. In fact, there seems to be rather little turbulence and not always complete mixing of blood during this "intraventricular" streaming from the inflow side to the outflow region. This explains why the streamlining of flow in the venous circulation is not always completely interrupted by the passage of blood through the ventricle. For example, the systemic venous blood is transferred into the pulmonary arteries in such manner that superior caval blood reaches predominantly the right lung and inferior caval blood the left lung [see also Bucher *et al.* (27)]. Obviously, the possibility of incomplete mixing deserves attention when samples of so-called mixed venous blood are drawn.

How much does the velocity of the blood flow decrease during the transit in the ventricle? In the resting organism with a slow heart rate, the velocity of blood streaming into the ventricle toward the end of diastole is rather small, as may be surmised from the fairly flat portion of the ventricular volume curve. When the cardiac output is elevated, the velocity of the intraventricular flow during isovolumetric contraction will probably increase for two reasons: 1) the velocity of end diastolic ventricular inflow increases through a shortening of diastole due to high heart rates and through a more forceful atrial contraction; 2) the transit time through the ventricle is shortened by the more powerful and often shorter myocardial contraction. Such higher intraventricular flow velocities under sympathetic activity could then result in a better energy conservation by not letting the speed of blood flow slow down too much before ventricular ejection begins again.

[It is the feeling of the editors that there is not sufficient evidence to show that continued translocation of blood within the ventricular cavity during isovolumetric contraction could contribute significantly to the subsequent ejection. Ed.]

2-4: *Rapid and reduced ventricular ejection.* As soon as the pressure in the ventricular cavities exceeds that in the aorta or the pulmonary artery, the blood is suddenly ejected. Although flow is created by a difference between the intraventricular and arterial pressures, an inspection of pressure curves alone, simultaneously recorded from the ventricle and the root of the artery, furnishes only meager information about the rate of volume flow and its time course. However, from simultaneously recorded flow and

FIG. 15. Phase relationships between pressure and flow as revealed by simultaneously recorded curves from the ascending aorta of a conscious dog. *Upper tracings:* rate of volume flow measured with a permanently implanted electromagnetic flowmeter. *Lower tracings:* aortic pressures obtained through a permanently implanted cannula leading to a strain gauge manometer. *A:* curves from the quiet reclining animal. *B:* curves from the animal running behind a car during moderate exercise. [Original curves by the courtesy of Frederick Olmstead, Cleveland Clinic, Cleveland, Ohio (personal communication, 1961).]

pressure curves in the aorta or in the pulmonary artery, the process of ventricular ejection is now fairly well understood [Wetterer (155)]. The ejection starts abruptly (fig. 15). The blood column in the root of the aorta, which is practically stationary at the end of diastole and during isovolumetric contraction, is rapidly accelerated and pushed toward the periphery. The greatest flow acceleration occurs during the steeply ascending limb of the aortic pressure curve, so that the highest flow rate (peak of the flow curve) is actually reached prior to the summit of the pressure curve. When the flow then becomes less rapid, the phase of reduced ejection is said to begin. The border between rapid and reduced ejection is quite arbitrary. When only pressure and cardiometer curves were available [Wiggers (156)], it was difficult to determine from the gradual leveling off of the downward limb of the volume curve when the rapid ejection started to slow down. The summit of the ventricular pressure curve was thought to indicate the end of rapid ejection (fig. 14). It is now known that the flow slows down earlier, since the peak of the flow curve definitely precedes the peak of the ventricular or aortic pressure curve (upper tracings

in fig. 15). The fact that the ventricular and aortic pressures continue to rise even after the flow rate starts to drop is not surprising, since during the period of reduced ejection, blood continues to accumulate in the aortic arch. Because aortic pressure at any one instant is determined both by the distention of the arterial walls with blood coming from the ventricle and by the runoff into the periphery, the pressure continues to rise as long as more blood enters the aortic arch than runs off toward the periphery. There is no fixed and easily definable time relation between the summits of the flow and pressure curves, because the factors determining the position of each of the summits are numerous and variable (149).

Some aspects of the time relation between the flow and pressure curves *A* and *B* are illustrated in figure 15. During exercise the rapid ejection occupies a relatively shorter portion of the total ventricular ejection. In this example the whole ventricular ejection lasts 374 msec at rest and only 234 msec during exercise. However, the delay between the summits of the flow and pressure curves is 109 msec, in both cases, or 29 per cent of the whole ventricular ejection at rest, and 46 per cent during exercise. In other words, during exercise the aortic pressure continues to rise relatively longer after the aortic flow rate has started to drop, indicating that there is relatively more blood accommodated in the central arteries (arterial compression chamber) during systole. This also means that, when ventricular ejection ceases, there is a higher aortic pressure and consequently a larger amount of peripheral runoff during early diastole. Such conditions help to maintain greater tissue perfusion in the active organism.

The configuration of the aortic flow curve is not the same in the organism at rest and during exercise or sympathetic stimulation. At rest, the descending limb of the flow curve first declines gently, then progressively faster, forming thereby a shallow hump (see fig. 15*A*). During exercise the ascending limb is steeper and the descending limb declines precipitously (fig. 15*B*). This pattern indicates: 1) an increase in the myocardial contractile force, which continues to exert its strong effect after the end of the isovolumetric contraction phase and achieves a more rapid flow acceleration; 2) a longer duration of flow at near maximal velocity (Olmstead, personal communication); and 3) a faster return to the beginning of myocardial relaxation. Despite shortening of the ejection phase, the stroke volume, which can be calculated from the area under the curve, is approximately the same during moderate exercise as it is at

rest. However, during strenuous exercise (running of dog at 16 miles per hour over rough terrain) the stroke volume appears to be increased by approximately 25 to 40 per cent (Olmstead, personal communication). Whether or not there is always an increase in stroke volume during exercise is still a matter of debate among various investigators [see also Rushmer (139)].

Toward the end of the reduced ejection phase the intraventricular and aortic pressures drop quickly. The ejection stops and forward flow in the ascending aorta ceases shortly after closure of the semilunar valves as seen by the crossing of the flow curve through the horizontal zero flow line in figure 15. Flow in the root of the aorta near the valves momentarily reverses its direction, because of a translocation of blood into the sinuses of Valsalva and the coronary vessels, which helps to close the aortic valves. Although there is a brief backflow near the valves, in the more distal part of the aorta the flow continues forward for a while, since the energy momentarily stored in the distended aortic arch propels the blood to the area of lower pressure, i.e., the peripheral vessels (compression chamber effect). The precise moment of valve closure cannot be easily correlated with the pressure and flow curves. It can be stated from the flow curve that the valves must have closed at least by the time when the downward deflection is suddenly stopped (fig. 15) and after which blood again is propelled forward in the ascending aorta. How much blood is regurgitated into the ventricles and how much flows into the coronary arteries while the valves are in the process of closing, has not yet been determined.

4-5: *Isovolumetric relaxation.* It is also difficult to establish the exact moment when the myocardial fibers start to relax after maximal shortening. Wiggers (156) took the steepening of the decline in the ventricular pressure curve prior to the deepest point of the aortic incisura as the beginning of the relaxation process and referred to the brief interval from the beginning of muscular relaxation to semilunar valve closure as the protodiastolic phase. Since little is gained by singling out this interval, which cannot be accurately measured, the phases of protodiastole and isovolumetric relaxation will be treated here as a single process as Wiggers (159) also suggested in his recent discussion on this subject.

It appears reasonable to assume that, just as the contraction began asynchronously, some myocardial fibers will begin to relax earlier than others. However, no direct measurements are available to document this hypothesis. At the end of isovolumetric relaxation,

FIG. 16. Phase relationships between aortic pressures, Ao ; left ventricular volume, LV , (dots); atrial volume, LA , (open circles); and electrocardiogram, ECG , in an anesthetized normal dog with a spontaneous heart rate of 110/min. The pressure tracings were simultaneously recorded and correlated with the volume measurement from the kinematographic frames. the intraventricular pressure drops to the level of the atrial pressure. The pressure decline, like the pressure rise, is more rapid under the action of epinephrine (158, 124) and apparently also in exercise. Therefore, with epinephrine and during exercise the duration of the isovolumetric relaxation phase is shorter for the same pressure difference between the incisura and atrial pressure. Neither the precise moment of the valve opening at the end of isovolumetric relaxation nor the pressure difference necessary to actuate them has been satisfactorily determined as yet. One usually takes the decline in atrial pressure after the V point as an indication that the atrioventricular valves have just opened and flow through the orifice has begun. The crossing over of the atrial and ventricular pressure tracings is therefore taken as the end of isovolumetric relaxation. However, even with the most careful recording, it is difficult to establish such a crossing over without artifacts. Since at this part of the cardiac cycle the heart has become a low-pressure system, instrumentation errors are commonly experienced with positioning of pickup devices, movement artifacts, lack of sensitivity, Bernoulli effect, and lack of a common and reliable reference zero pressure level.

5-7: *Rapid and slow ventricular filling.* There is no satisfactory procedure to measure directly the inflow of blood from the atrium into the ventricle. The best information stems from X-ray kinematographic studies such as those of Rushmer (139), Chapman *et al.* (31, 32), Gribbe *et al.* (56). A good time resolution was obtained by Gribbe, who took 40 to 50 frames per sec using an image intensifier. The individual frames of film were projected and the volume was

calculated from the contrast silhouette of the left atrium and ventricle, assuming that the left ventricular cavity resembles an ellipsoid of rotation. Figure 16 illustrates the steep upward slant of the curve during the phase of rapid ventricular filling. The incline of this part of the curve is even steeper than the decline of the curve during rapid ventricular ejection, indicating that blood actually rushes into the ventricle faster than it is ejected from the ventricle. This observation has an important bearing upon the concepts of the forces which bring about ventricular filling (see later section). After the rate of ventricular inflow has reached its maximum, it begins gradually to slow down until finally the curve tends to level off. There is no distinct break which could serve as a criterion for precise determination of the end of the rapid filling phase and the beginning of the slow phase. Nevertheless, the distinction between these two phases remains useful at slow heart rates, as for instance under strong vagotonic influence, because the slow phase of ventricular filling then lasts much longer than depicted in figure 16.

7-1: *Filling by atrial contraction.* With the contraction of the atrial myocardium an additional volume of blood is pushed into the ventricle, as shown by the sudden final incline of the curve in figure 16. The contribution of atrial contraction to ventricular filling has been much debated [see Mitchell *et al.* (113)]. According to the measurements of Gribbe *et al.* (56), it should amount to about 20 to 25 per cent of the volume entering the ventricle. Atrial pressure drops after the peak of atrial systole but seemingly without a measurable decrease in ventricular volume by backflow through the atrioventricular valves. If

ventricular pressures are recorded with instruments of sufficient sensitivity, the transfer of the atrial pressure rise can be observed on the ventricular pressure tracing, since atrium and ventricle form a common cavity during atrial systole. Similarly, after the peak pressure of atrial systole has been reached, the pressure drops not only in the atrium but also in the ventricular cavity. When the atrioventricular valves actually close is still a matter of debate (see also later section). It may well be that the large valve leaflets begin to approximate each other at the moment when the atrial pressure starts dropping and that they continue to move toward each other because ventricular blood flows into the large spaces behind the closing leaflets. Therefore, the valves may start to close at a time when the ventricular pressure is decreasing slightly. Complete closure would then be achieved when the dropping atrial and intraventricular pressures level off (Z point in atrial pressure curve).

As the heart rate becomes faster under sympathetic stimulation or in exercise, the period of slow ventricular filling is progressively shortened by an earlier onset of the atrial systole [see Mitchell *et al.* (113)]. At heart rates above 120 per min the phase of slow ventricular filling is more or less abrogated (56). Figure 17 illustrates how at a heart rate of 160 per min the phase of rapid ventricular filling is directly followed by the inflow due to atrial contraction. In these curves one cannot discern the usual hump in the upstroke of the filling curve which occurs when rapid ventricular filling changes to slow ventricular filling before the atrium adds its contribution. It is likely that at still faster heart rates, the atrial component of the curve blends completely with the inclined tracing characteristic of rapid ventricular filling. At extreme degrees of tachycardia even the phase of rapid ventricular filling may be encroached upon. This would explain why the stroke volume decreases at very rapid heart rates since there is not sufficient time for adequate filling of the ventricle.

The force of atrial contraction usually varies concomitantly with that of ventricular contraction. Therefore, the percentile contribution of atrial systole to ventricular filling is lower under vagal influence and higher under sympathetic excitation. In extreme tachycardia, when atrial systole begins during the phase of rapid ventricular filling, the actual contribution of the atrium to the filling of the ventricle may be as high as 30 to 40 per cent. The atrial contraction would then serve to increase the pressure difference between the atrium and ventricle in the later part of the rapid filling phase and thereby

FIG. 17. Phase relationships among aortic pressure, left ventricular volume (dots), atrial volume (open circles), and electrocardiogram (ECG), in an anesthetized normal dog with a spontaneous heart rate of 160/min. The pressure tracings were simultaneously recorded and correlated with the volume measurement from the kinematographic frames. produce a maximal velocity of inflow throughout the entire, though brief, phase of rapid ventricular filling.

CORRELATION OF OTHER CARDIAC EVENTS WITH THE CARDIAC CYCLE

The time sequence of cardiac events originally described by Wiggers (156) was based upon those pressure changes in the circulatory system which were measurable at the time. However, during the last three decades our trend of thinking about cardiac events has been greatly affected by the progress of electrocardiography. At the very beginning of the investigations of the field (about 1910-1920) the electrocardiogram could only be correlated secondarily with the time course of the more easily measurable pressure events (138). Nowadays one can record electrocardiograms with a higher degree of time resolution than intracardiac pressures. For this reason it is rather common to use the electrocardiogram as the basis or guideline for dividing the cardiac cycle into phases and then to fit secondarily the pressure and flow events into the patterns of the electrical events (17, 157). However, there is a varying time lag between electrical and mechanical events under different experimental conditions [see Luisada & Liu (104)], so that such a correlation system is not entirely satisfactory.

Atrial Pressures

The recording of atrial pressures is beset with considerable experimental difficulty, as is the case with all fast changing phasic events in low pressure systems. The finer details of atrial pressure contours are therefore often affected by artifacts from impacts or vibrations which make it difficult to arrive at accurate deductions concerning atrial flow dynamics. Indeed the atrial pressure pulse contour depicted in figure 14 is highly schematized.

Atrial pressure begins to rise at the onset of atrial systole (A wave). Since at this moment the atrium and ventricle form a common cavity, the height which the atrial pressure attains is influenced by the volume distensibility characteristics both of the atrium and of the ventricle, in addition to the rate of translocation of the fluid from one part of the cavity into the other. The resistance to flow through the normal atrioventricular orifice is so low that it cannot be measured with presently available techniques.

Little is known about the synchronicity or asynchronicity of the contraction of atrial muscle fibers. The excitation wave spreading over the atrial walls proceeds from the sino-atrial node. Therefore it can be assumed that the contraction, which follows depolarization after a brief interval, similarly proceeds in a wave. The concept of asynchronous atrial muscle contraction is based on the premise that the delay between depolarization and contraction is the same for all atrial muscle fibers. It is not certain that this is the case. A contractile wave is difficult to demonstrate conclusively and consistently by means of slow motion pictures.

The drop in atrial pressure, after the pressure has reached a peak during atrial contraction, is probably caused by the beginning of atrial muscle fiber relaxation. Again, it is not possible to state whether this occurs synchronously or in a sequential order and to state what effect this process has on the flow dynamics. From the configuration of the atrial pressure curve one cannot necessarily infer the exact onset of atrial muscle relaxation. Just as the ventricular pressure curve can still rise although the rate of ejection already declines (see fig. 15), the atrial pressure could well start to decrease before or after the relaxation in the atrial musculature actually begins. The convention of calling the leveling off of the declining atrial pressure curve the "end of atrial systole" is also arbitrary [Opdyke *et al.* (126); Opdyke & Brecher (125)].

There is often a brief period (Z point) during which the atrial pressure curve remains level after its decline

from the systolic rise. This is the last moment at which the atrial and ventricular cavities are probably still in communication before complete closure of the atrioventricular valves. The atrial Z point pressure is almost equal to the ventricular end-diastolic pressure because the rate of ventricular inflow has become minimal at this moment. Therefore it is fairly safe to take the Z point as a representative of end-diastolic ventricular pressure. It is definitely more accurate to use the Z point than the mean atrial pressure, which depends upon numerous factors unrelated to the end-diastolic ventricular pressure, such as integration of artifacts and peaks at the A, C, V points (126).

After the Z point the atrial pressure often rises briefly and precipitously (C wave). This pressure rise, frequently accompanied by vibrations, is ascribed to the bulging of the atrioventricular valves into the atrial cavity during ventricular isovolumetric contraction. Immediately following the sharply peaked C wave, atrial pressure usually declines to a level corresponding to atmospheric zero in an open-chest preparation (see fig. 14), or to near-zero transmural pressure in a closed-chest organism. It is believed that this pressure drop is caused by the pull of the papillary muscles on the atrioventricular valve leaflets and by the descent of the atrioventricular junction which suddenly enlarges the atrial cavity. The bottom of the pressure drop is called the X point (or wave). Thereafter atrial pressure rises slowly up to the V point (or wave) located at the end of ventricular isovolumetric relaxation. The pressure rise from the X point to the V point is probably caused by an inflow of blood which distends the atrial walls. The atrial pressure drop (Y point or wave) after the opening of the atrioventricular valves results from the rapid transfer of blood into the ventricular cavity in which a lower pressure prevails. While it is assumed that the actual opening of the atrioventricular valves occurs at the summit of the V wave, there is some debate whether or not it occurs slightly afterward [see also Nixon (120)].

A minor change in the conventional labeling of atrial pressure tracings has been used by Kaplan (88). Without mentioning the Z point, he refers to the small decline in pressure which frequently follows atrial systole, before the C wave, as the X wave. Then he designates the pressure decline after the C wave as the X¹ wave. There is no conspicuous advantage to this system of notation.

Electrocardiogram

Since the electrocardiogram is easily obtainable and serves as an important diagnostic tool, considerable efforts have been made by theoretical and clinical scientists to correlate timewise electrical and mechanical events of cardiac contraction. Nearly half the large volume of the *Physiology of the Heart*, by Schütz (144), is devoted to this subject and should be referred to for detailed information.

From the standpoint of cardiac pumping, the electrocardiogram is principally of interest insofar as it may furnish a convenient method of determining precisely the course of mechanical events without resorting to surgical interventions, cannulations, etc. Present attempts along these lines are still inadequate. They are also theoretically limited for the following reasons: *a)* although the electrical event always precedes the mechanical event, it is not known whether the time intervals between depolarization and beginning of contraction are identical in all heart muscle fibers. *b)* There may be differences in the rates of impulse propagation along various fibers resulting in varying rates of contraction once depolarization has started at one point. *c)* As repeatedly emphasized by Rushmer (139) and Scher (142), there is considerable mechanical asynchronicity in the contraction of cardiac muscle fibers, which cannot be completely unraveled by recording the over-all electrical changes from a large mass of tissues such as the heart. *d)* There are possibly time differences between the right and left heart depolarizations and contractions, but these differences are inconstant and change with various factors.

An example of the difficulties encountered in attempting to establish empirical time correlations in the cardiac cycle is shown in figure 18. Using normal anesthetized dogs, Gribbe *et al.* (57) studied the volume changes in the cardiac chambers with cineradiography and timed the events with the conventional electrocardiogram. Comparison of the time relations in figure 19 with those shown in figures 14 and 18 reveals considerable discrepancies.

Vibrocardiogram (Apex Cardiogram)

The intracardiac pressures are not easier to correlate with the electrocardiogram than with a number of other mechanical events [e.g., Harrison *et al.* (65)]. For instance, the classical mechanocardiogram or apex cardiogram, now often referred to as precordial vibrocardiogram, offers a good example of the present limitations in the description of the

FIG. 18. Schematic presentation of the relationship between electrical and mechanical events. Heart rate 120 beats/min. The markings in lower part of the figure indicate the picture frequency at an exposure rate of 48 frames/sec. 1, Onset of right atrial contraction; 2, onset of right ventricular contraction; 3, onset of right ventricular ejection; 4, end of right ventricular ejection; 5, onset of right ventricular filling; 6, onset of left atrial contraction; 7, onset of left ventricular contraction; 8, onset of left ventricular ejection; 9, end of left ventricular ejection; 10, onset of left ventricular filling. The striped areas represent the phase of ventricular isovolumetric contraction. The stippled areas represent the phase of ventricular ejection. [From Gribbe *et al.* (57).]

cardiac cycle. Figure 19 shows a composite chart made up of superimposed schematized tracings as they are observed in normal man. The chart has been constructed by Agress *et al.* (2) from the most appropriate tracings which they could find in the recent literature. The authors state: "Although this is a composite graph, an accuracy of 0.005 second per scale division was made possible by using a simultaneously inscribed electrocardiogram as the time base." It is evident that claims for an accuracy of 5 msec can be only referred to the electrocardiogram, since the time definition of intracardiac pressure recording through long catheters is usually poorer than 0.005 sec. This fact is not pointed out in criticism of the well-deserving attempts to correlate the various events of the cardiac cycle in man, but only for the purpose of cautioning against hasty conclusions.

Agress *et al.* (2) divide the cardiac cycle into phases, which differ slightly from those customarily accepted in the past. The curves (fig. 19) are intersected by vertical lines based on the time relation of left atrial and left ventricular pressures, as indicated by the upper margin band, *L*, of the graph and the small heart schemes above it. The phases are labeled

FIG. 19. Composite graph of the events of the cardiac cycle in the human heart. For discussion see text. [From Agress *et al.* (2).]

in the next lower band, where *P.S.* stands for protosystole and *P.D.* for protodiastole. The lowest band of the upper margin, *R*, illustrates the time difference between the activities of the right and left heart. A number of points warrant brief comments. For all intracardiac and arterial pressures a common zero is used. The "low" pressure events (left atrium, right ventricle, and pulmonary artery) are plotted on a scale from 0 to 45 mm Hg (left), whereas the "high" pressure events (left ventricle and aorta) are graphed on a scale from 0 to 150 mm Hg (right). The use of two different pressure scales for correlating simultaneous events on the same time basis results in different slopes. The casual viewer may hastily conclude that the rate of pressure rise during isovolumetric contraction is greater in the right ventricle than in the left ventricle, which is actually not the case. Correspondingly, the pressure drop during ventricular isovolumetric relaxation appears to occur faster on the right than on the left side, which does not happen either. The ascending limbs of the aortic and pulmonary arterial pressure curves have been obtained from overdamped recording systems, such as often happens with long catheters. This might explain why the tracings of the arterial pressures have gentle slopes and remain considerably below the summits of the ventricular pressure curves. An interesting innovation is the protosystolic phase (*P.S.*) which apparently extends from the leveling off of the left atrial A wave until the beginning of the left ventricular pressure rise. It seems to correspond to the conventional Z point. According to the tracings in figure 19, the protosystolic phase appears to be timewise closely related to the electrocardiogram. It seems to last from the beginning of the Q wave until the tip of the R wave. The usefulness of introducing this distinctly different phase seems to lie in the easy correlation of certain characteristics of the phonocardiogram and vibrocardiogram with the cardiac cycle during this time interval.

A number of other cyclical events occurring in the circulatory system also can be more or less accurately correlated with the cardiac cycle. Examples would be: various peripheral arterial and venous pressure pulse curves as well as flow pulse curves; intramyocardial pressures (96); the ballistocardiogram; electrokymogram (42, 163, 135); angiokymogram (147); angiocardiogram; cardiorheogram (3, 68); and heart sounds [Luisada *et al.* (105)]. In all cases the previously mentioned difficulties in precise timing must be given serious scrutiny. A discussion of all

events which lend themselves to correlation would exceed the scope of this chapter.

FUNCTION OF THE HEART VALVES

Valves are essential for efficient action of all reciprocating pumps in order to maintain unidirectional flow. Valves must offer a minimal impedance to flow, yet be able to close abruptly with minimal leakage and minimal displacement. The heart differs from a mechanical pump in that a perfect seal must be obtained in orifices which are continuously changing in shape, size, and position throughout the cardiac cycle. Therefore, the valves must be somewhat larger than the area to be covered in order to remain competent under all normal working situations. The heart valves are also located in orifices beyond which the blood enters wider chambers. This provides for a rapid stream along the axis of the orifice, with decrease in lateral pressure at, and just beyond, the restricted valvular plane (Bernoulli effect) and possibly the production of eddy currents. This mechanism keeps the valves floating in the blood stream and insures rapid approximation of the valve leaflets as soon as the axial stream of blood ceases.

The movements of the atrioventricular and semilunar valves are passive since the valve leaflets do not contain muscle fibers [see also Moritz (116)]. The consideration of this aspect is important because it is easier to replace passive structures by prostheses than it is to create prostheses for active structures such as muscles. It is also possible to investigate the forces involved in the movement of passive structures by observing the function of a prosthesis which simulates a natural organ in suitable physical analogues. Davilla (36) summarizes this trend of thought as follows: "The most successful prostheses have been those which fulfill a passive role in the functional complex: a metal plate on the skull, a nail in a long bone, steel or plastic mesh in a weak abdominal wall, a tube of cloth to replace a blood vessel. . . . Fortunately, the role of the cardiac valves in hemodynamics is a passive one. They are not parts that move but parts which are moved. Their role is identical to that of a simple check valve. It is their environment which complicates the matter. They are immersed in flowing tissue which is chemically unstable but which must not be subjected to extreme unbalance; which possesses a clotting mechanism that must not be activated by the valve; and which transports vital cells that

must not be traumatized. The valves must open and close an orifice which continuously changes in size and provides scant room for support between pulsatile and irregular chambers. The motion of the valves depends upon cardiac action and must be coordinated with those structures which impart it. And, finally, the valvular apparatus must withstand the stress of beating more than forty million times a year during the life span of the subject."

In a multichambered pump such as the heart, valves or valve-like mechanisms are expected at each boundary between functionally separate chambers. We shall therefore discuss the function of the structures which prevent backflow: *a*) at the veno-atrial junction; *b*) at the atrioventricular junction; *c*) at the ventricle-arterial junction.

Veno-Atrial Junction

In adult mammals the sinus venosus is completely incorporated in the atrium and there are only remnants of "valves" which are incapable of preventing backflow into the superior caval vein (valvula Eustachii) or in the coronary sinus (valvula Thebesii). In the left atrium there is not even the most rudimentary valve to prevent backflow in the pulmonary veins. Nevertheless, there are some structures which may contribute to prevent backflow from the atria, such as circular muscle fibers around the pulmonary veins and the coronary sinus, and a complex system of more or less discrete muscular bundles around the orifices of the caval veins. It has been speculated that these fibers contract very early in atrial systole and that by a narrowing of the orifices a valve-like or sphincter-like action occurs [see also Kjellberg & Olsson (91), Burch & Romney (28), Campeti *et al.* (30)]. This would prevent or at least diminish backflow of blood from the atria into the venous trees at the beginning of atrial systole. Although backflow from the atria into the caval veins can be frequently observed and quantitatively registered with flowmeters (18) and contrast media (14), the amount of backflow is surprisingly small as compared to the amount of blood simultaneously pushed by the atria into the ventricles. The precise mechanism by which backflow is kept so small is still enigmatic (144). An interesting light has been cast upon this problem recently by Little (101). He determined pressure-volume curves in the left atrium of dogs during temporary ventricular asystole. His findings suggest that upon a slight rise in atrial pressure above the pulmonary venous pressure there is a closure of the

pulmonary veins near their atrial junction. This closure, apparently brought about by collapse of the vein in a critical region, prevents regurgitation of blood from the atrium into the pulmonary bed. However, at high atrial pressures the closed segment opens and blood flows into the pulmonary veins.

Atrioventricular Valves

The atrioventricular valves are funnel-shaped structures inserted on a fibrous ring. They are developed as an ellipsoidal diaphragm and separated by commissures into somewhat independent cusps, the edges of which delineate the valvular orifice (37, 38). The commissures do not extend all the way to the valve ring (see fig. 3). Traditionally, one distinguishes two cusps on the mitral valve and three on the tricuspid valve, although both valves essentially consist of two large opposite cusps and a variable number of small intermediate cusps at each end of the ellipse [see also Rusted *et al.* (140)]. The strands of collagenous fibers known as chordae tendineae extend from the papillary muscles either to the free edge of the cusps (first order chords) or to a few millimeters beyond the edge (second order chords), or even quite far back into the substance of the valve through a kind of "goose foot" forked insertion (third order chords). The anatomy of papillary muscles is quite variable. One usually recognizes in the right ventricle three groups of papillary muscles to which the tricuspid valve is fastened, whereas there are usually two such groups to fulfill the corresponding function in the left ventricle. The chords are of unequal length, so that probably the same tension is exerted on each at the time the valve closes. The chords from adjacent regions of opposite cusps are inserted on the same or adjacent papillary muscles, in order to insure leakproof closure [see also Brandt (15), Hubacher (82)].

The exact mechanism of closure of the atrioventricular valves has been the subject of much debate [Kantrowitz *et al.* (87)]. The old theory of closure mainly by active contraction of the papillary muscles has been abandoned, and the role of active contraction of muscular fibers at the base of the valves just after atrial systole is taken as either minor, or nonexistent [see also Little (100)]. The decisive factor is probably the onset of ventricular contraction, which establishes a higher pressure in the ventricle than in the atrium. It can be shown that whenever the ventricles begin to contract, there is a retrograde

flow of blood toward the atria which catches the valves like a pair of sails and flings them into apposition. As pointed out by Rushmer (139) this mechanism inevitably involves a leak before the orifice is closed. The occurrence of such regurgitation is widely acknowledged when the atrioventricular valves are closed by a ventricular systole which is not preceded by atrial contraction, i.e., "premature ventricular contraction" [see also Paul *et al.* (128)]. Since the normal wave of excitation propagated by the Purkinje fibers enters the ventricular myocardium over the endocardial surface, at the roots of the papillary muscles, the early contraction of papillary muscles draws the valve edges toward the apex and thereby produces some shortening of the ventricular chamber with a resulting passive lateral displacement of the ventricular walls. During ventricular ejection, the decrease in ventricular volume is accompanied by a further shortening of the papillary muscles, taking up any slack in the valves which might develop.

It has been suggested that under normal conditions, the valves approximate, i.e., begin to close before the onset of ventricular contraction, although it is difficult to substantiate this view by chronologically precise measurements. Many explanations have been advanced for this: passive, upward movement of the valves at the end of diastole caused by retrograde flow of blood along the ventricular wall, or by elastic recoil of the ventricular wall to the strain of atrial systole (8); eddy formation beyond the valves during atrial systole (102); or development of a wave of negative pressure as atrial inflow abruptly ceases [Henderson & Johnson (70)]. Through these mechanisms, the atrioventricular valves are approximated or almost closed just before ventricular systole. Then, when the ventricular myocardium contracts, the valves are completely closed to prevent backflow into the atria.

The concept of a presystolic approximation of the atrioventricular valves received considerable impetus when Dean (37) succeeded in obtaining direct recording of the valve movement in an isolated, surviving heart. Dean demonstrated that when the interval between atrial and ventricular systole is sufficiently long, there is indeed a rapid movement of the valves toward the atrium at the end of atrial systole, followed by a second period of separation of the cusps just before the onset of ventricular systole. When the period of ventricular filling is shorter (at faster heart rates) there is no time to observe separately the effects of atrial systole and of ventricular systole. Then there is "only a single closure move-

ment beginning before ventricular systole, a single movement due in part to auricular contraction and in part to ventricular contraction" (37).

The extent to which the valves and their attachments move in the intact organism has been recently questioned by Rushmer (139). Having observed that exposed or excised hearts tend to shrink, he and his associates surmised that the valves might have much less slack under their normal operating conditions than reported by previous investigators. They used cinefluorography to observe the movements of the mitral valves which had been marked with tiny metal clips at a previous operation. These studies demonstrated that the excursion of the valves, at least where the metal clips were placed, toward the atrium is remarkably small, and pointed to a more or less continuous restraint by the chordae tendineae.

Arterial Valves

The aortic and pulmonary valves consist of three symmetrical cusps attached, similarly to suspension bridges, around the circumference of the valve orifice (see fig. 3). When the cusps are approximated they form a starlike figure; when open, they delineate a nearly rounded but still somewhat triangular orifice of an area slightly smaller than that of the artery. At the tip of each triangular valve leaflet, where the three valve leaflets come in contact, there is a discrete thickening called the nodulus Arantii. There are also thin, membrane-like structures (lunulae) on the free edges of the valves on either side of the noduli. Normally the free edges come into contact surface against surface rather than border to border. Toward the valvular orifice, the ventricular musculature assumes the shape of a funnel (*conus arteriosus*), whereas beyond the valves at the origin of the aorta and pulmonary artery there are three outpouchings which provide some free space behind the valve cusps even when they are maximally opened.

The mechanism of action of the arterial valves can be described as follows. During ventricular ejection, the blood stream opens the valves from below and a rapid flow is established along the axis of the valvular orifices. However, the valves are not pushed flush against the arterial wall. On the contrary, eddy currents, generated by the axial jet of blood, swirl in the spaces behind the cusps. Indeed, the action of turbulent eddies is such that the faster the ventricular ejection, the closer to the center of the axial stream the valve edges are brought [Hochrein (76)]. Thereby the valves are prepared to close almost instantane-

ously as soon as ventricular ejection ceases. It is likely that contractions of muscle fibers in the conus arteriosus tend to make the valve rings more narrow during ejection, as discussed in an earlier section. In this manner axial velocity of flow is increased and turbulence, which may prepare the valves for closure, is enhanced. At the end of systole when ejection ceases, the forward movement of blood in the root of the artery continues for a very brief period. Then, the action of the eddies on the upper surface of the valves prevails over the force exerted from below (rapidly falling intraventricular pressure). Hence the retrograde surge of blood toward the ventricle (see fig. 15) is arrested by valve closure, and marked pressure differences between the relaxing ventricle and the elastically distended aorta can develop.

VENTRICULAR AND ATRIAL VOLUMES IN VARIOUS ACTIVITIES

Certainly one of the most important features of a pump is the volume which can be propelled per stroke. This is easy to measure in a mechanical pump, but it requires complex and sophisticated instrumentation to determine the stroke volume of the intact heart. Successful attempts in this direction have recently been reported, e.g., by Rushmer (139) and his school, by Hawthorne (67), and by Olmstead (personal communication). Nevertheless, numerous questions remain still unanswered, namely, *a*) the quantitative correlation of the stroke volume with the other parameters of cardiac activity, and *b*) the relationships of the ventricular stroke volume to the volumes remaining in or passing through the atria, the ventricles, and the large vessels. At the present time most of these questions can only be approached under highly controlled situations which limit the significance of the experiment. Discrepancies are therefore encountered depending upon the method of approach used. At this point, it must also be remarked that heart volumes have traditionally been measured by X-ray or cardiometer techniques which include the volumes of the walls. Only recently have radiopaque dyes and other media been developed which permit measuring the content of the cardiac cavities and not their over-all volumes (56). Consequently a large part of the data incorporated in the literature require critical attention. In this chapter, the word "volume" refers exclusively to the liquid content of the cardiac cavities and excludes the volume oc-

cupied by the walls and by the blood-filled vessels or channels in the walls.

Ventricular Volume

To describe the changes in ventricular volumes under dynamic conditions, it is advisable to review the modern terminology introduced by Rushmer (139). This terminology is illustrated and somewhat expanded in figure 20 by drawing a parallel between the familiar lung volumes (left) and the ventricular volumes (right).

The stroke volume of the organism at rest corresponds to the tidal volume of respiration. In exercise the ventricle can also eject some of the blood which at rest would remain in the ventricular cavity at the end of systole. Rushmer suggests the term "systolic reserve volume" for that additional amount of blood which is not ejected under resting conditions, but can be maximally ejected with a more forceful contraction. This corresponds to the expiratory reserve volume of the lungs. The volume of blood left in the ventricle after a normal systole used to be called "residual volume." Rushmer restricts the term residual volume to that amount of blood remaining in the ventricle after maximal ejection. Then the term corresponds truly to the lung residual volume. The ventricle can also increase its stroke volume by an augmented venous return during diastole and subsequent ejection of this extra volume in addition to the resting stroke volume. The term "diastolic reserve volume" defines the maximal amount of blood which the ventricle can receive and then eject in addition to the normal diastolic inflow. This volume corresponds to the inspiratory reserve volume of the lungs. The resting stroke volume, systolic reserve volume, and diastolic reserve volume together define the maximal stroke volume, which corresponds to the vital capacity of the lungs.

The parallelism can be carried even further (fig. 21). In the resting organism, the amount of blood remaining in the ventricle at the end of ejection (called by some authors the "end-systolic volume") would best be referred to as functional residual capacity since it is now customary to use the term capacity for the sum of two or more "volumes." ("Capacity" does not imply something that is absolute or fixed, despite the unfortunate analogy suggested by the age-old and uneradicated expression "vital capacity.") The functional residual capacity of the ventricle comprises the systolic reserve volume plus residual

FIG. 20. Scheme of lung volumes (*left*) and ventricular volumes (*right*) at rest and during exercise or sympathetic stimulation. For details see text.

FIG. 21. Scheme of lung volumes (*left*) and ventricular volumes (*right*) at rest to illustrate the parallelism between respiratory and ventricular volumes.

volume, much as the functional residual capacity of the lungs comprises the expiratory reserve volume and the residual volume. Correspondingly, the amount of blood accumulated in the ventricle at the end of ventricular diastole (often called the end-diastolic volume) could be referred to as "diastolic capacity," including the stroke volume plus systolic reserve volume plus residual volume. Since the stroke volume varies with changes in activity, the diastolic capacity is not a fixed amount but functionally variable. It becomes larger as the stroke volume increases and smaller as the stroke volume decreases. There are two more terms which can be described in parallelism with the nomenclature used in respiratory physiology. The volume level reached at the end of systolic ejection is termed "end-systolic level" and corresponds to the expiratory level of the lungs. The volume level reached at the end of diastolic filling is called "end-diastolic level" in analogy to the inspiratory level of the lungs.

The importance of a clear terminology for the description of the dynamic shifts of ventricular volumes under varying conditions of activity has been pointed out by Rushmer (139) and many others have followed his lead. The parallel with the lung volumes also permits useful analogies. For instance, an increase in residual volume of the lungs in emphysema diminishes the ventilatory efficiency. In a somewhat similar manner an increase in the ventricular residual volume, such as occurs in excessive ventricular dilatation, diminishes the pumping efficiency of the heart.

To compare with the cardiac ventricles, a piston pump would need the following features. The course of the piston, which defines the stroke volume, would have to be limited in order to leave fluid in the pumping chamber at the end of ejection (functional residual capacity). If a greater output were needed, the piston would have to push farther and increase its stroke volume by encroaching upon the systolic reserve volume. Yet the volume filling the dead space of the pump (residual volume) could never be ejected. The diastolic reserve volume would be represented by a farther pulling back of the piston to allow greater filling of the pump chamber. In this mechanical system, the need for a greater output could be met instantaneously by the ejection of part of systolic reserve volume. However, the diastolic reserve volume could not be utilized instantaneously because the pump chamber has first to be filled to a greater extent before more can be ejected. The situation seems to be the same in the heart. The left ventricular

stroke volume can be increased from one heart beat to the next by drawing upon the systolic reserve volume, as occurs for instance when the organism passes abruptly from rest to exercise (33, 139, 146). On the contrary, the mechanism of greater diastolic filling (Starling's law) always involves a brief delay brought about by the need for greater venous return before increased ejection. Apparently, only in strenuous exercise and in some pathological conditions is the diastolic reserve volume called upon.

Indeed the ventricular stroke volume varies almost continuously and is not identical from beat-to-beat even under resting conditions. Some of the variations are probably caused by the fluctuating play of poorly known neural feedback processes. Others are caused by mechanical forces such as those which accompany respiration. In fact the respiratory variations of the ventricular stroke volume are remarkable even under resting conditions (21). Figure 22 shows the typical changes in right ventricular output during five heartbeats modified by the action of one respiratory cycle. After the onset of inspiration, *A*, there is first an increase in venous inflow (second heartbeat) and then in ventricular stroke volume (third heartbeat). Similarly, the drop in venous return during expiration (at the fourth heartbeat) is reflected by a decrease in stroke volume one beat later. From this record it appears that the right ventricle temporarily accommodates part of the large inspiratory inflow of venous blood, and releases it into the pulmonary circulation during the respiratory pause. This indicates that with respiration not only the stroke volume varies but also the functional residual capacity (or end-systolic level).

The functional residual capacity cannot be measured directly in the intact organism. Most of the estimates obtained with indirect methods display considerable variation according to the technique employed. The volume curves shown in figures 16 and 17 were obtained with multiple plane high-speed X-ray cinematography. They show not only the volume changes throughout the cardiac cycle, but also the end-systolic level. The functional residual capacity of the left ventricle of these 12-kg dogs amounts to approximately 5 to 6 ml. In unanesthetized, quiescent dogs, the values measured were of the same order of magnitude. Gribbe *et al.* (56, 57) estimate that on the average the stroke volume of dogs is 60 per cent of the diastolic capacity. Thus functional residual capacity amounted to 40 per cent of the diastolic capacity. It should be pointed out that Gribbe's values are much smaller than the

FIG. 22. Effect of spontaneous respiration on right ventricular stroke volume, measured by the directly recorded pulmonary blood flow in an anesthetized normal dog. The simultaneously recorded pattern of right atrial filling (represented by superior vena cava flow), arterial, venous, and intrathoracic pressures permit a time correlation. Tracings from top to bottom: time and base line, aortic pressure in mm Hg, pulmonary artery, superior vena caval and intrathoracic pressures in mm water, pulmonary arterial and superior vena caval flows in ml/min. *A* = beginning of inspiration; *S* = acceleration of superior vena caval flow during ventricular systole; *D* = acceleration of superior vena caval flow during ventricular diastole. Stroke volume (in ml) entered under pulmonary artery flow curve. Flow (in ml) through superior vena cava during each cardiac cycle entered at bottom of record. Electrical frequency response of both flowmeters reduced from 400 to 40 cycles/sec. Superior vena caval pressure curve damped. [From Brecher & Hubay (21).]

estimates of Holt (77) with dye dilution techniques, which range from 30 to 76 ml for a dog of 15 to 16 kg in weight. This enormous discrepancy cannot be reconciled at present. Simultaneous determinations under rigidly controlled conditions with both methods, the cineangioradiography and the indicator dilution technique, may elucidate this point.

That the situation is equally unsettled for measurements in man is shown by the work of Rushmer (139), Chapman *et al.* (32), Nylin (122), Reindell *et al.* (134), Folse *et al.* (47), Lüthy (personal communication, and 106). Generally, determinations using roentgenologic technique furnish smaller values for the functional residual capacity than measurements with dye dilution techniques. For instance, Folse *et al.* (47), employing radio-iodinated Diodrast, found in 20 resting persons that the left ventricular

stroke volume averaged 42.2 ± 8.8 ml per m^2 of body surface area. The diastolic capacity averaged 90 ± 26 ml per m^2 (functional residual capacity 48 ml/ m^2). On the other hand, Lüthy (106) found with thermodilution techniques that in normal patients the left ventricular stroke volume amounted to 45 ml per m^2 of body surface (range 39–57 ml/ m^2) but the diastolic capacity to 145 ml per m^2 (range 128–173 ml/ m^2). According to these data the stroke volume would be only one-third of the diastolic capacity [39%, Folse *et al.* (47); 31%, Lüthy (106)] whereas, in the dog it is apparently about two-thirds (60%, Gribbe).

The problem is further complicated by the fact that the ratio of stroke volume to functional residual capacity changes markedly under various normal and pathological conditions. This is well illustrated by the observation that a great increase in resistance to ventricular ejection (e.g., in extreme hypertension) causes the heart size to become much larger while the stroke volume decreases. This implies a large increase in the functional residual capacity. Direct evidence for an increase in functional residual capacity under this condition is the observation that, when the aortic resistance is suddenly reduced by opening of an arteriovenous shunt, the first stroke volume is twice the normal size [Hamilton (61)]. From the foregoing it is obvious that much more information based on direct measurements of heart volumes under various conditions is needed.

Atrial Volume

The volume of blood contained in the atrium at any time has evoked much less interest than the ventricular volume. No quantitative information has been available until recently. Even the terminology of atrial blood volumes is more difficult to define than that of ventricular volumes. During two phases of the cardiac cycle (isovolumetric contraction and isovolumetric relaxation), the ventricle contains a definite volume because the atrioventricular and semilunar valves lock the ventricular content. The atria, however, are always open on the venous inflow side. On the outflow side they are closed only from the beginning of isovolumetric ventricular contraction to the end of isovolumetric ventricular relaxation. Consequently, the volume contained at any one instant represents the balance of almost continuously changing inflow and outflow.

The changes in atrial volumes can be understood by following the atrial volume curves (open circles)

in figures 16 and 17. The left atrial volume is greatest during isovolumetric relaxation of the left ventricle. During the rapid ventricular inflow phase the atrial volume decreases rapidly, but not so fast as the ventricle fills. This indicates that some blood enters the atrium from the veins while at the same time a greater amount leaves it toward the ventricle. During the phase of slow ventricular inflow (diastasis) the atrial volume remains practically unchanged, pointing out that inflow from the veins and outflow toward the ventricle are approximately in balance. Incidentally, this gives a measure of the rate of venous return to the atrium during this phase by simply calculating the increase in ventricular volume. During atrial systole (approximately end of P wave of electrocardiogram, fig. 17) the atrial volume decreases precipitously. The rate at which the atrial volume decreases and the ventricular volume simultaneously increases speaks in favor of a negligible backflow of atrial blood into the veins during atrial systole. At the peak of atrial systole the volume of blood contained in the atrium is minimal, but still amounts to approximately 4 ml in dogs. During the phase of isovolumetric ventricular contraction, the atrial volume already begins to increase owing to an accelerated venous inflow. It continues to increase at a rather fast rate during rapid ventricular ejection and at a slower rate during the phase of reduced ventricular ejection. Whereas the ventricular stroke volume of the 12-kg dog amounts to about 8 ml, the difference between the largest and smallest atrial volume amounts to only 5 ml. This indicates that during the ventricular rapid and slow filling phases approximately 3 ml passes from the veins through the atrium into the ventricle without being recorded as an atrial volume increase. It further indicates that during ventricular isovolumetric contraction, rapid and reduced ventricular ejection, about 5 ml pass from the veins into the atrium while the atrioventricular valves are closed.

Obviously, one expects during exercise a greater accommodation of blood in the atrium during ventricular ejection and a greater outflow of blood from the atrium into the ventricle during the ventricular rapid and slow filling phase. There are still no measurements available concerning such physiological adaptations. It appears reasonable to suggest that in exercise the atrium ejects during its own systole a greater volume, thereby drawing upon the amount of blood usually remaining at rest in the atrium at the end of atrial systole. This might be termed the "atrial systolic reserve volume."

ATRIAL FILLING

The phasic changes of venous return which bring about atrial filling are still a subject of debate. It is often stated that venous blood returns to the heart solely as a result of the force imparted to it on the arterial side of the circulation (*vis a tergo*). Yet there are reasons to believe that the systolic contraction of the ventricular myocardium also contributes to atrial filling by causing an expansion of the atria [see also Hamilton (60) and Holzlöhner (79)]. This view was originally advocated by Purkinje (132) who observed that during ventricular systole the atrioventricular junction (the plane of the heart valves) descends toward the apex and pulls on the atrial walls. The atrial cavity is then passively expanded and the pressure in it drops, causing an acceleration of blood from the veins into the atria. Among functional anatomists, the concept of the attraction of blood into the atrium by the descent of the valvular plane toward the apex during ventricular systole has gained great favor. By injecting drops of radiopaque contrast material into peripheral veins and taking X-ray cinematographic pictures, Böhme (14) could demonstrate a remarkable acceleration of central venous flow during ventricular systole. Records obtained from direct measurements of blood flow in the superior and inferior venae cavae with a high fidelity flowmeter by Brecher & Praglin (25) and by Brecher (19) confirmed Böhme's observations. It appears now that ventricular contraction does cause a sudden expansion of the atrium. This mechanism lowers the pressure in the atrium and produces the X wave, much as a plunger withdrawn in the barrel of a syringe lowers the pressure therein. The expansion of the atrium probably begins with the asynchronous contraction of the papillary muscles during the early part of the isovolumetric phase and continues during rapid ventricular ejection. In the hands of Rushmer (136, 139) the lipiodol injection technique indicated only a moderate acceleration of caval blood flow during early ventricular systole [see also Lynch (107)]. However, Rushmer's findings can be reconciled with those of Böhme and Brecher, if one considers the differences in the various experimental conditions (open or closed chest, anesthetized or awake animals, slow or fast heart rate, inspiration, expiration, volemic status, etc.). The measurements of Gribbe (56, 57) in intact closed-chest animals definitely indicate an increased atrial inflow beginning at isovolumetric ventricular contraction and continuing during the rapid phase of

ventricular ejection (see atrial volume curve in fig. 16 and superior vena cava flow curve in fig. 22). In Chapter 17, vol. I, of this *Handbook*, evidence is given that in normal man the venous stream toward the heart pulsates reciprocally to the aortic stream leaving the chest. The exactitude of the reciprocal relationship is said to be measured by the very small volume equivalent of the cyclic changes (cardiac) in intrathoracic pressure after making allowance for the elasticity of the chest walls (60, 64).

In conclusion, the filling of the atrium during ventricular systole depends not only upon the pressure of blood in the venous reservoir which is available for passive filling from behind; it depends also on the vigor with which ventricular systole moves the atrioventricular junction. Thus a more forceful contraction (commonly associated with a larger stroke volume) ensures additional inflow into the atrium and therefore facilitates the next ventricular ejection without the need for further decreasing the systolic reserve volume to maintain a large stroke volume. The increase in ventricular outflow and in atrial inflow are mediated by the same force, ventricular contraction, and both favor a more thorough filling of the ventricle during the next diastole.

The central veins are most suitable for this reservoir function because through partial collapse of their walls, their content can change rapidly without much change of pressure. They form a collapse chamber which is the functional counterpart of the aortic compression chamber (18). On the arterial side, the compression chamber based on the elastic distensibility of the walls assures the transformation of the discontinuous cardiac ejections into steady flow to the tissues. On the venous side, the collapse chamber based on the pliability of the walls assures at the atrial entrance the transformation of the steady flow from the tissues into the pulsatile flow which is needed for the discontinuous cardiac filling [see also Irisawa *et al.* (83)].

The filling of the venous collapse chamber is in turn aided by the atrial systole. From a hemodynamic standpoint the function of atrial contraction is two-fold: 1) It ejects some blood into the ventricular cavity, a well-established fact, and 2) it passively enlarges the central venous reservoir by briefly slowing down or stopping atrial inflow. The small amount of backflow which is often recorded during atrial systole at the caval-atrial junction normally does not extend far into the periphery (18). It is readily taken up by a widening of the collapse chamber and, together with the continued inflow

from the periphery, creates the pool from which the next ventricular filling derives its supply.

Any force which lowers pressure in a region toward which flow occurs, is called suction, whether or not the pressure developed in that region drops below atmospheric zero. Physically "suction" is the same as pressure (force per area). It is a reduction of pressure at some point in a system by the application of a force which results from an energy conversion process, e.g. muscular contraction, elastic recoil, pulling of a plunger. Since blood is attracted into the atrium by ventricular contraction, one may therefore state that atrial filling is at least in part brought about by suction upon the venous blood mediated through a stretching and enlargement of the atrial cavity by the contracting ventricular muscles which cause a descent of the atrioventricular junction. This phenomenon can be termed "ventricular systolic suction" upon the atrial content.

[A semantically more rigid definition of the concept of "suction" holds that suction can be thought of only in locations where the transmural pressure is negative (142). Accordingly suction cannot be transmitted through viscera (atria, veins) which have collapsible walls. As long as these viscera contain blood at a greater pressure (including equivalent kinetic energy) than the extra visceral pressure, the dominant force is "pressure" from upstream rather than "suction" from downstream. This pressure maintains the walls of the atria and intrathoracic veins under elastic tension during the entire cardiac cycle. Ed.]

When the atrioventricular valves open during ventricular diastole, there is another decrease in atrial pressure (Y wave), which results once more in an acceleration of venous blood inflow into the atrium. This second acceleration is more pronounced at slow heart rates and is usually greater in closed-chest than in open-chest animals. Apparently the expansion of all the cardiac cavities through the pulling force of the lungs [Pfuhl (129, 130)] helps to make the atrial inflow during ventricular diastole slightly greater than during ventricular systole. The increase in atrial inflow during ventricular diastole may also be a consequence of the attraction of atrial blood into the ventricle through the forces which expand the ventricle during diastole (ventricular diastolic suction, see following section). These forces not only affect the blood contained in the atrium but in turn even affect the adjoining veins by lowering the atrial pressure, particularly during the phase of rapid ventricular filling. Figure 22 illustrates the phasic increases in superior vena caval flow during ventricular systole (S) and during ventricular diastole (D) in an anesthetized closed-chest dog.

In summary, ventricular myocardial contraction could have a threefold effect upon atrial filling: 1) It imparts so much energy to the arterial stream that even after passing through the capillaries, the blood continues to flow in the veins and fills the central reservoirs; 2) during ventricular systole blood is drawn actively into the atrium through an expansion of the atrial cavities by a movement of the atrioventricular junction toward the apex ("ventricular systolic suction"); 3) during ventricular diastole the elastic forces, created by the preceding systole in the ventricular walls, can aid in drawing blood from the atrium into the ventricle and even in attracting blood from the veins into the atrium ("ventricular diastolic suction" upon the atrial content).

VENTRICULAR FILLING

While the forces causing ventricular ejection are unquestionably those originating from myocardial contraction, there is considerable debate concerning the forces responsible for ventricular filling [for details see Brecher (19), Krug & Schlicher (95), Eldridge & Hultgren (41), Bauereisen *et al.* (7)]. The ejection of fluid from a pump is more spectacular than the filling phase. This may be the reason why the forces dealing with ventricular contraction have received considerably more attention than the forces dealing with ventricular filling. For a long time it has been believed that the heart is filled exclusively by a force which pushes blood into the ventricle from behind [*vis a tergo*, Galli (50)]. This force results from the preceding ventricular contractions and is imparted to the blood for circulating it through the arteries, capillaries, and veins. Others have maintained that some part of ventricular filling is produced by a force from the front (*vis a fronte*) which attracts or sucks blood from the atrium into the ventricle. This force would manifest itself in the ventricle during diastole and would probably be caused by an elastic recoil of the ventricular walls. It would lower the intraventricular pressure below the level which would prevail if such a *vis a fronte* did not exist. The history of the issue between *vis a tergo* and *vis a fronte* is treated in detail by Ebstein (40), Hamilton & Lombard (64), Böhme (14), Brecher (19, 20), Krug & Schlicher (95). One can summarize as follows the evidence in favor of the existence of a *vis a fronte*: Ventricles of cold-blooded animals, in the observations of Kraner & Ogden (94), Kraner (93), Hennacy & Ogden (73), Hennacy (72),

Peiper & Weigand (131), and of mammals according to Bloom (13), Fowler *et al.* (48, 49) Brecher (19), and O'Brien (123), can definitely suck in blood when the filling pressure at the atrioventricular orifice is atmospheric (zero) or subatmospheric (negative). Whether or not ventricular suction also contributes to ventricular filling in the presence of a positive filling pressure at the atrioventricular orifices has not yet been experimentally established.

It has been objected that the ventricles in which suction forces were demonstrated had an abnormally small functional residual capacity. The question therefore arises whether or not ventricles with physiological volumes would also exert a suction force. Scheu & Hamilton (143), using the intact spontaneously breathing anesthetized dog, made simultaneous recordings of the intraventricular and thoracic pressure and thus established the transmural ventricular pressure gradient. They held that "suction," probably by the elastic recoil of the ventricular walls, could be demonstrated only if and when the transmural pressure was negative. They concluded that suction did not occur during normal diastole but could be brought about by compressing the mitral orifice or by hemorrhage. These two maneuvers made the diastolic ventricular shadow smaller and were thought to have reduced the residual blood to a subnormal figure.

Brecher & Kissen (23) demonstrated that dog ventricles of an approximately normal functional residual capacity filled by suction at zero ventricular inflow pressure. Nevertheless, as long as there is not unequivocal experimental proof of the existence of ventricular diastolic *vis a fronte* in the unanesthetized intact mammalian organism, one should be exceedingly cautious with any statement concerning the role of diastolic suction in ventricular filling [Brecher (20)].

Horres and his group (unpublished observations) determined the average left ventricular volumes of excised submerged hearts at equilibrium state and found it to be 17 (± 6) ml for dogs weighing 12 kg (fig. 23). If one assumes that the elastic equilibrium state of the relaxed ventricle *in vivo* is the same as that of the freshly excised, and still responding ventricle *in vitro*, then diastolic ventricular suction could occur at any ventricular volume below the equilibrium point (i.e., less than 17 ml). Unfortunately the values of the functional residual capacity reported for the dog heart vary too much to permit an unbiased conclusion about the role of suction in ventricular filling. According to the data of Holt

FIG. 23. Relationship of ventricular volume (V.V.) and body weight (B.W.) in dogs. Ventricular volume measured at the equilibrium state (zero transmural pressure). [See also fig. 2 (Horres *et al.*, unpublished observations).]

(77) the average functional residual capacity of the left ventricle would be approximately 30 ml for dogs weighing 12 kg. According to Gribbe *et al.* (57), it is only 5 ml. The discrepancy between Holt's and Gribbe's measurements in terms of ventricular diastolic suction is illustrated in figure 24. If Holt's data are correct, ventricular diastolic suction never occurs under normal conditions. On the contrary Gribbe's figures speak for the occurrence of diastolic ventricular suction during all phases of diastole. Obviously the controversy cannot be resolved on the basis of presently available data.

There has been some speculation about the possible nature of the frontal force, particularly whether it originates from an active or a passive process. An active process would be the contraction of muscle fibers which, owing to their anatomical arrangement, could widen the ventricular cavity during diastole [Guasp (58)]. There is no experimental evidence to support such a view. Another active process would be the development of a force acting to lengthen the muscle fibers upon completion of their contraction ("active decontraction"). However, it has never been satisfactorily demonstrated that processes of energy conversion from chemical to kinetic energy occur during muscular relaxation [Villa (152); for review, Brecher (19, 20)]. The most acceptable evidence is, at present, that the diastolic ventricular vis a fronte is caused by passive processes, such as one of the following. *a*) During systole an interfascicular tension develops through shear forces between myocardial strands which contract to different extents and asynchronously [details in Rushmer (139)]. *b*) During systole noncontractile elements in

the heart and possibly also some components of the muscle fibers are elastically deformed beyond their equilibrium state, thereby storing potential energy which is released through elastic recoil during diastole (see fig. 2). *c*) In the closed-chest mammal, additional external forces residing in the elastic recoil of the lungs exert their effect upon the heart by tending to expand the cardiac cavities beyond the size these cavities would assume in the absence of the lung forces.

In conclusion, some of the classical views concerning the filling of the heart may need revision. The ventricle acts as a reciprocating pump in which the output stroke simultaneously provides energy for the filling of the pump for the next stroke. In other words, the heart does not act merely as a pressure pump as William Harvey (66) believed, but it actually functions as a pressure-suction pump [see also Gauer, (52, 53)]. The amount of energy necessary for pump filling is, however, only a fraction of that needed for ejection, since the filling occurs through a fluid transfer into a low resistance system in which small pressure differences will cause a rapid flow of large amounts of blood.

DIFFERENCES BETWEEN RIGHT AND LEFT CARDIAC CAVITIES

Functional differences between the right and left cardiac cavities can be expected from their anatomical characteristics. Yet it had long been tacitly assumed that the two atria and the two ventricles initiate and terminate their contraction simultaneously, and that a description of cardiac events on both sides would be redundant.

In fact, there are significant differences between the left side and the right side chambers [see also Katz (89), Hamilton *et al.* (62), Luisada & Fleischner (103), Segers (145), Braunwald *et al.* (16), McKusick (109)]. For instance, at equal pressures the right atrium has a volume twice that of the left atrium, which is thicker and less distensible than the right (99). Experimentally, the volume-pressure curve relationship in the left atrium has been found to be linear only as long as the pressure remains within the normal limits (pressure below 150 mm H₂O). When this limit is exceeded, a slight increase in volume causes a much larger increase in pressure. The normal level and patterns of pressure also differ somewhat between the right and the left atrium. The A wave of the right atrium, produced

FIG. 24. Functional residual capacity of the dog's ventricle and its relation to ventricular diastolic suction. *Left*: data derived from Holt (77), assuming that a functional residual capacity of 50 ml in a 20.9-kg dog corresponds to 30 ml in a 12-kg dog (regression line of fig. 23). *Right*: data of Gribbe *et al.* (56) for a 12-kg dog. *Center*: elastic equilibrium state of the ventricle in a 12-kg dog (Horres *et al.*, unpublished observations).

by atrial systole, is often not so steep and tall as that of the left atrium, and normally precedes it slightly. The peak of the right atrial V wave is usually lower than that of the left atrial V, and the mean right atrial pressure is usually less than the left atrial pressure.

At the level of the ventricles the bundles of myocardial fibers which encircle the two cavities, much as the windings of a turban, belong to a common anatomical structure. The combined effect of their contraction is to wring blood out of the ventricular chambers into the respective arteries. Yet the muscular arrangement is such that contraction of the left ventricle produces primarily a reduction in the lateral diameter with only a moderate shortening along the vertical axis, whereas on the right side there is much ventricular shortening between apex and base with relatively less pulling of the free wall toward the septum. The mechanical effects of left ventricular contraction occur a trifle earlier than those of right ventricular contraction, since the rise in right ventricular pressure usually lags by 0.01 to 0.02 sec behind the rise in left ventricular pressure (see also fig. 19). It is, therefore, understandable that mitral valve closure usually precedes tricuspid valve closure. Nevertheless, it is by no means established whether the later start of right ventricular contraction is the only cause of asynchronicity. Other factors could also operate, such as a faster rate of contraction of the left ventricular wall or a quicker reaction of the mitral cusps to the rising wave of pressure in comparison with the tricuspid valve. The characteristics of the vascular bed into

which ejection proceeds cause differences in the sequence of pumping events on the right and on the left side. Since the pressure in the pulmonary artery is low (low resistance to flow in the pulmonary vascular bed), the pulmonary valve opens first. Indeed, for an interval of about 0.02 sec, the ventricular contraction produces an ejection on the right side while there is still an isovolumetric pressure rise on the left side. Similarly, right ventricular ejection continues well after cessation of left ventricular ejection. In other words, the end of left ventricular systole precedes that of the right and closure of the aortic valve precedes closure of the pulmonary valve. On the other hand, because of a much longer phase of isovolumetric relaxation in the left ventricle as compared to the right, the opening of the mitral valve is thought to follow that of the tricuspid, as seen in table 1, which is borrowed from Luisada & Liu (104) and summarizes the sequence of events of right and left ventricular contraction (see also figs. 18 and 19).

Because of these differences in the pumping action of the ventricles, reference is often made to right and left ventricles as being a "volume pump" and "pressure pump," respectively. Implied in this nomenclature are the facts that the right ventricle can easily handle an increase in volume output without apparent strain, whereas it is not so well equipped for raising its pressure to a high level. On the contrary, the left ventricle, with a much larger mass of active musculature and a more nearly spherical geometry is better able to face an increase in out-flow resistance than the right ventricle. What is

TABLE 1. *The Cardiac Cycle. Time Intervals Between Valvular Motions (Normal Dogs)*

| Event | Interval, in Sec |
|----------------------------------|------------------|
| Q wave (ECG) | 0.06-0.07 |
| Closure of mitral valve | 0.00-0.02 |
| Closure of tricuspid valve | 0.01-0.03 |
| Opening of pulmonic valve | 0.01-0.02 |
| Opening of aortic valve | |
| Closure of aortic valve | 0.02 |
| Closure of pulmonic valve | 0.03-0.04 |
| Opening of tricuspid valve | 0.04-0.08 |
| Opening of mitral valve | 0.00-0.04 |
| Rapid filling of right ventricle | 0.04-0.08 |
| Rapid filling of left ventricle | |

Each peak of rapid ventricular filling follows A-V valve opening by 0.08-0.10 sec, and the closure of the respective semilunar (i.e., pulmonary or aortic) valve by 0.12-0.18 sec. This table shows the sequence of events in normal, large dogs, whose figures are probably very close to those of normal man. [From Luisada & Liu (104).]

meant by the terms "volume pump" and "pressure pump" is actually "low-pressure head pump" and "high-pressure head pump."

There is no fundamental difference in the pumping action of the two ventricles before birth. They both receive blood from a common atrial chamber, their walls are of the same thickness, they have the same capacity, and they both eject their contents into a common aortic chamber via either the ductus arteriosus or the ascending aorta. The pressure against which the fetal ventricles eject their contents is lower than that in the adult systemic circuit, but after birth the resistance in the lesser circuit drops suddenly with the first breath, whereas that in the systemic circuit gradually increases. The difference in pumping action that prevails in the normal adult exists essentially because of the difference in resistance to flow.

In the adult the resistance to flow in the pulmonary vascular bed is estimated to be only about one-eighth of that in the systemic circulation. On the other hand, it is estimated that a sizable amount of the mechanical energy, both pressure and kinetic, imparted to the blood by left ventricular ejection is still available at the point of venous inflow into the right ventricle, and is partly responsible for right ventricular filling and distention during diastole (*vis a tergo*). Connecting these two observations, one may wonder whether right ventricular contraction is necessary at all, or whether the left ventricle alone could not only circulate the blood through the systemic vascular bed but also through the pulmonary

vascular bed. The problem has been approached in different ways. It was first observed that major destruction of the right ventricular wall (by cauterization, for instance) causes but slight changes in systemic venous and arterial pressure [Bakos (5), Kagan (86)]. Yet a doubt remains, since some inner layers of the right ventricular wall are left intact in such experiments, and conceivably contractions of muscular bundles, which belong to the left ventricular wall, could still pull on passive strands of the remaining right ventricular wall and thus indirectly eject blood through the pulmonary ostium. In such a case, the noncontracting cauterized remainder of the right ventricular wall would passively compress the half-moon-shaped right ventricular cavity. Also, the still intact, powerful ventricular septum could contribute to the right ventricular systolic pressure rise. Acute experiments in which the entire heart is arrested and only the left ventricle, but not the right, is replaced by a mechanical pump, indicate that apparently stable circulatory conditions in both the systemic and the pulmonary vascular beds can be maintained using a single "left ventricle" pump [see also Rodbard & Wagner (137), Jamison *et al.* (85), Warden *et al.* (154), Patino *et al.* (127), Nuland *et al.* (121), Monod-Broca (115), Glenn (55)]. Obviously, the pressure in the vena cava is then raised to maintain sufficient pressure for the pulmonary circulation, and there may be an impairment to cerebral, coronary, and hepatic venous outflow. However, the conditions are compatible with survival of the animal. The question is not solely of academic interest, since it is not impossible to envision that some day surgical techniques will be devised to drain the entire systemic venous return directly into the pulmonary artery, thereby placing the entire load of circulation on the left ventricle.

THE PERICARDIUM

The function of the pericardium in the cardiac pumping process has been the subject of much debate. Some authors consider that the pericardium does not affect cardiac performance, because congenital absence of this structure in man is compatible with maintenance of a seemingly normal cardiac function [see Ellis *et al.* (43) and Hering *et al.* (74)]. Others have speculated that the primary function of the pericardium is to confine in space the pumping structures which are characterized by their expansi-

bility, pliability, and limited anchorage [see Pfulf, (129) and Nelemans (118)]. A number of additional functions have been ascribed to the pericardium, namely: protection of the entire heart from over-dilatation; protection from over-dilatation of the left ventricle only; protection from over-dilatation of the right ventricle only; increase of cardiac performance because of higher filling pressure; better harmonic coordination of right and left ventricular contractions; facilitation of atrial filling; and facilitation of the gliding of the epicardium through lymph lubrication.

Most experimental studies on the function of the pericardium concern abnormal situations such as are met in pericardial effusion and tamponade from various other causes [Feinberg (46), Adcock *et al.* (1), Evans *et al.* (44), Nerlich (119), Metcalfe *et al.* (112), Isaacs *et al.* (84), Bencini & Parola (9)]. The information from these studies, though in some respects limited to abnormal hemodynamic situations, has contributed much to the elucidation of normal functions of the pericardium.

Since some of the functions are implicit from the architecture of the pericardium, a brief anatomical-histological review will be helpful (118). The parietal pericardium, generally just called pericardium, forms a thin, but firm sac of connective tissue enveloping the ventricles and atria. At the base of the heart, near the entry of the veins into the atria, the parietal pericardium joins the visceral pericardium or "epicardium." Pericardium and epicardium are separated by a thin fluid film of pericardial liquor which is similar to the fluid filling the intrapleural space. The outer aspect of the pericardium is covered with a thin layer of loose connective tissue which constitutes the pericardial, or parietal, pleura. The pericardium is attached to the diaphragm with two septa (right and left) to the sternum and to the mediastinum. This anchorage limits the mobility of the sac and in turn confines the heart to a definite space within the thorax, especially in primates.

Histologically the pericardium consists of three layers of regularly oriented collagenous and elastic fibers, each oriented in a different direction. The fibers of the outer and middle layer form a thicker structure than those of the inner layer. In a preparation which is not submitted to stretch, the collagenous fibers appear wavy and the elastic fibers appear straight. Nelemans (118) showed that with an acute dilatation of the normal heart, the pericardium extends itself by approximately 20 per cent until the elastic fibers are markedly stretched and the

FIG. 25. Pericardial pressure-volume curve in a dead dog, determined after removal of heart. The volume of the heart is replaced by fluid injected into the pericardial space. [From Holt (78).]

rather tense collagenous fibers hinder further expansion. This elastic stretching is quickly reversible, since the sac will again fit snugly when cardiac dilatation is abrogated. If, however, the heart dilates beyond the limit of elastic stretch, which obviously can only happen if venous return and end-diastolic pressures rise substantially, then the pericardium will "give" or yield. However, this additional stretching is not quickly reversible and persists for a long time after the heart has returned to its normal shape, as evidenced by the slackness of the pericardial sac. The additional stretching is of "plastic" nature and can be attributed to the collagenous fibers which return only very slowly to their previous length after stretching. This dual mechanism of "elastic" and "plastic" stretch hinders acute overinflation (elastic limitation) but permits long term dilatation of the heart (plastic adaptation).

Nelemans' (118) views concerning the "plastic" behavior of the pericardium are supported by observations made in experimental pericardial effusion: following the infusion of 50 ml of saline into the pericardial sac in an open-chest dog, the mean intrapericardial pressure first rises markedly but then gradually decreases to a lower level. Withdrawal and immediate reinfusion of the same amount of fluid results in a lower pressure than the one initially obtained. Withdrawing the saline, but then waiting for about 2 hours before reinjecting it, results in

approximately the same pressure rise as initially recorded upon the first infusion.

The pressure-volume relationships of the pericardial sac without the heart were recently studied by Holt *et al.* (78) in experiments which emphasize the relatively nondistensible nature of the pericardium. The curve in figure 25 illustrates that, as the fluid volume in a dog's pericardial cavity increases, the pressure remains at zero until the volume has reached about 200 ml. Further volume increments cause a rather steep rise in pericardial pressure. The results of these and other experiments [Isaacs *et al.* (84), Berglund *et al.* (11)] point to an important function of the pericardium, i.e., to restrain the heart's cavities from overdistention.

In 1914, Henderson & Prince (71) showed that the filling-force relationships which later became known as Starling's law were such in the right and left ventricles as to prevent the engorgement or depletion of the lung blood. The lungs were further safeguarded against congestion by the fact that a sudden dilation of the left ventricle within the pericardium would prevent the filling of the right heart, limit the amount of blood that could be pumped into the lungs and thus prevent their engorgement.

There has been much debate as to whether during diastole the heart normally fills the entire pericardial sac [see also Wilson & Meek (162)]. Nelemans (118) concluded that the heart fills the pericardium completely during diastole and that the sac has a restraining influence upon the expansion of the heart. However, this question has not been studied extensively until modern recording techniques enabled Holt *et al.* (78) to follow the phasic changes of intracardiac and intrapericardial pressures during the cardiac cycle under various filling conditions ranging from hypovolemia to plethora. It was found that in an open-chest dog any increase in ventricular end-diastolic pressure above approximately 1 mm Hg causes a nearly equal rise in pericardial pressure. Since end-diastolic pressures of this order of magnitude are found under normal circulatory conditions, it appears that the ventricle does occupy the pericardial sac completely and even stretches it slightly at the end of the filling phase. Since under conditions of plethora a positive pressure is maintained in the pericardial space throughout the cardiac cycle, the transmural ventricular or transmural atrial pressure must then be taken as the difference between intracardiac and pericardial pressures rather than as the difference between intracardiac and intrapleural pressures.

In comparing the phasic changes in intra-atrial, intraventricular, and pericardial pressures, Holt *et al.* (78) also made observations which cast light on the contribution of the pericardium to the pumping action of the heart by facilitating atrial filling. The pericardial pressure drops markedly during the early part of ventricular systole. "Since the atria are located within the pericardial sac . . . , the pressure in the right atrium decreases in early systole and the atrium becomes distended by blood rushing into it from the great veins. A measure of the degree of this atrial 'filling pressure' is the difference between right atrial end diastolic pressure and the pericardial pressure in early systole." When the atrial pressure drops, "the pressure gradient from the great thoracic veins to the right atrium is markedly increased. This appears to be a mechanism by which blood is drawn into the atrium during ventricular systole, and in this way blood is ready to fill the ventricles immediately on cessation of ventricular systole. Thus, with the pericardium intact, the act of ventricular systole draws blood to the ventricle [sic] and insures ventricular filling in early diastole. These results are in agreement with those of Böhme and Brecher who showed that there was a large sudden flow of blood through the superior vena cava toward the heart during early ventricular systole. This has been attributed by several investigators, and most recently by Brecher, to the sudden piston-like downward movement of the atrioventricular junction attracting blood from the central veins into the right atrium. Our data indicate that the increased flow into the right atrium is caused by the sudden decrease in pericardial pressure with ventricular systolic ejection, and that this factor becomes greater with higher ventricular diastolic pressures. Confirmation of the importance of the pericardium in this connection is the observation of Brecher that the acceleration of venous flow toward the right atrium during ventricular systole is decreased by opening the pericardium. It would appear that the increased flow into the right atrium during ventricular systole was caused in large part by the decrease in pericardial pressure during early ventricular systole. The question as to how much of this flow is caused by a downward movement of the atrioventricular junction remains unanswered. Quantitative data on this point could be obtained by measuring the flow into the right atrium in the open-chest dog, with the pericardium intact and after complete removal of the pericardium" (78).

Obviously, both the piston-like downward move-

ment of the atrioventricular junction and the drop of pericardial pressure during early ventricular ejection are caused by the same force, i.e., the ventricular myocardial contraction. Which of the two factors is predominant in facilitating atrial filling during ventricular systole will not be easily decided.

From the presently available evidence one can conclude that the pericardium aids the pumping function of the heart. In contradiction to the widespread opinion that the absence of the pericardium does not have a noticeable effect upon the circulation, there is some experimental evidence that a large percentage of pericardiectomized animals develop heart hypertrophy and perform poorly on the treadmill [see Nelemans (118)]. It is quite possible that under conditions of rest or mild exercise the heart without pericardium can satisfy the metabolic demands of the tissues. However, under conditions of strenuous exercise the reserve power of the heart without pericardium is probably diminished.

CLOSING REMARKS

In recent years the opinion has been often voiced that hemodynamics is a dead science, in which no more essential work needs to be done. This view refers primarily to the mechanical features of the cardiovascular system which are supposedly well known. It applies less to the regulatory aspects which admittedly require further clarification. However, the analysis of such a presumably simple function as the heart's normal pumping, even without consideration of any neural or hormonal regulatory processes, reveals wide gaps in our knowledge.

There are numerous reasons for these shortcomings.

Many of the measurements on which present concepts are based were obtained under highly artificial conditions, such as excised heart preparations and open-chest animals, which limit the applicability of the results to intact normal organisms. Findings in one animal species often cannot be transferred or extrapolated to other species. For instance, the mechanics of cardiac pumping in man differ from those in other animals because of his upright position, minimal splanchnic pooling, and several other factors. Finally, measurements are often performed with inadequate instrumentation. For example, errors caused by insufficient sensitivity and time resolution make it difficult to correlate simultaneous events in the cardiac cycle.

Only rather guarded conclusions can therefore be drawn from the available experimental evidence as to the exact nature of the heart's pumping function. Wide discrepancies of information obtained with different methods need to be reconciled. For example, measurements of the ventricular volumes by various methods differ so greatly in their order of magnitude that it is today still impossible to state how large is the normal functional residual capacity of the heart. Obviously, views based on insufficient data must remain in the realms of speculations and postulates. This is the state of knowledge about many age-old problems such as cardiac filling and the precise moment of valve closure. How much more complex these problems become under various pathological conditions does not need to be elaborated upon. In view of the recent progress in the biomedical sciences, it is shocking to observe how a seemingly simple mechanical process such as cardiac pumping still remains so enigmatic.

The help of Dr. Robert C. Schlant in reviewing the manuscript is gratefully acknowledged.

The physiology of the aorta and major arteries¹

JOHN W. REMINGTON *Department of Physiology, Medical College of Georgia, Augusta, Georgia*

CHAPTER CONTENTS

- Measurement of Aortic Distensibility
 - General Characteristics of the Tension-Length Curve
 - The Hysteresis Loop
 - Selection of Representative Curves
 - Histological Considerations
 - Effects of Active Muscular Contraction on Distensibility
 - Effects of Aging on Arterial Distensibility
 - Expression of Extensibility in Terms of Moduli
 - Changes in Length and Wall Thickness of Arteries
- Action of the Aorta as a Conduit
 - Pulsatile Flow in Rigid and Distensible Tubes
 - Quantitation of Fluid Displacement and Wall Distensibility Relationships
 - Phase Lag and the Harmonics of the Arterial System
 - Construction of a Hypothetical Ejection Curve
- The Aorta as a Blood Reservoir
 - Changes in Central Pulse Contour During Propagation
 - Resonance and Standing Waves
 - Other Factors Which May Alter the Central Pulse Contour
 - Calculation of the Stroke Volume From the Central Pressure Pulse

AT OUTSET, may I say that this article on the function of the aorta and the major arteries makes no pretense of being an authoritative review of the literature, and is not only a generalized treatment but is written with a bias. I came to cardiovascular study via Biology, in an era when Physics was not such a firmly trothed bride of Physiology. I do not think glibly in terms of abstract formulas, of electrical analogues, or the other erudite devices now so commonly used to clarify the complex problems which underlie pressure wave formation and propagation. I believe that I understand a process only when I can construct some

sort of a visual image of just how it operates. In many aspects of the subject such a visual model is at present impossible. I can only describe what I have been able to gather about the function of the major arteries, and speculate about what trends future research will follow.

These large arteries serve two clear functions. First, they comprise a network of conduits through which blood is moved from the centrally located cardiac pump to the various capillary beds. It is important that this transfer be made with a minimal loss of energy. The problem of proper conduit design became more acute when the body form became elongated, instead of remaining spherical. Second, the distensible wall of the vessels allows a temporary storage of blood during the ejection phase of the pump cycle, which allows a buffering of the oscillatory pressure changes. This aspect will be spoken of as the reservoir action of the vessels, admittedly an inadequate label. While the buffering action might serve to protect the small vessels from large pressure changes, it also involves considerable change in the conduit properties.

We cannot yet form a definitive analysis of the effectiveness of aortic design in meeting these fundamental requisites. Progress has been handicapped because it has been so difficult to make critical studies on intact vessels. Pressure changes at various points along the arterial system have been measured often over the past 50 years (1, 16, 18, 28-30, 40, 42, 99, 116, 132, 134, 135). This has given us knowledge, still far from complete, about the speed of pulse-wave propagation, the contour of the pressure pulse as formed in the upper aorta, and the changes in this form as the pulse moves into the distal aorta and large arteries. It is doubtful that any great progress toward an understanding of arterial dynamics will be made by

¹ This manuscript was completed January 15, 1961, and its references include only papers I had read in published form at that time.

further studies on pressure values alone, without a simultaneous recording of vessel diameter or flow.

A study of two parameters has often been attempted, but not too successfully. It has not proven practical to remove the aorta from the body and insert it into an artificial system where the volume change and the flow through might be measured directly, as from a calibrated stroke of a pump. The problems of coupling this distensible tube to rigid fittings without having an orifice that will severely distort the flow pattern are considerable. No effective means has been devised to occlude completely all exit vessels, including the vasa vasorum, and thus prevent loss of fluid along the length of the vessel. Sometimes a rubber insert has been used (137) but, since most rubber tubes are less extensible than the aorta, this stratagem may have confused matters more than it helped. And we still have no pump which has an ejection pattern like that of the ventricle. Curiously enough, an artificial pump capable of producing a pressure rise similar to that seen with a natural pulse invariably produces turbulence and vibrations of the pressure recorder sufficient to obscure the pulse contour being formed.

A recording of aortic flow *in vivo* by a technique which requires vessel cannulation causes enough distortion of the pressure pulse contours that one must be cautious in inferring a direct pertinence to the intact system. Fortunately, several techniques are now in use for the recording of flow (27, 31, 55, 82, 110, 120, 131) and the registration of diameter change (88, 91, 113) which do not require cutting the vessel. Most flow recorders do require a crimping of the vessel in the region where flow is being measured, which may not be without effect on the flow profile. As yet, the frequency of many such devices usually does not approach that of a good pressure recording system, so that they may not be able to give a faithful picture of rapid change.

An engineer faced with the problem of designing a conduit system for the most efficient movement of blood would start with some basic equations. First, there would be the Poiseuille formula which states that the pressure fall (for frictional energy dissipation) will be directly related to the flow rate, the fluid viscosity, and the length of pipe, and inversely related to the fourth power of the radius. The last is because adsorptive forces between the fluid and the wall prevent or retard longitudinal movement of the outermost fluid layer. This in turn forces the adjacent shell to shear past it, retarding it with a frictional dissipation of energy, which in turn slows the next shell of fluid, and

so on to the middle of the pipe. For a given volume flow, the greater the pipe diameter, the less is the total fluid frictional loss. He would also include in his formulas factors relating to the smoothness of the wall and the material of which his conduit will be made, since these condition the size of the boundary layer. He must make corrections if the fluid does not have a constant viscosity at all flow rates, as blood apparently does not (9, 86). He also knows that an equation which applies to laminar flow will not be correct if fluid molecules whorl laterally across the fluid shells, i.e., when the flow becomes turbulent. The frictional cost increases whenever this happens. Finally, when he is required to use pipes of different sizes, he must carefully design the transition areas so that turbulent eddies will not form. Tapered changes in diameter are less conducive to turbulence than abrupt shoulder joints.

All these formulas, which may be found in texts on hydraulics, are based on the assumption that flow is being maintained steady, and that the conduits have rigid walls. But blood flow is not steady, for it shows several accelerations and decelerations with each pump stroke. A calculation of the energy loss accompanying such rapid changes in flow rate must be complicated. A whole new set of equations will be required and, to check them, we must be able to measure precisely the amount of acceleration in all parts of the arterial system. Quantitative evaluations of the degree of smoothness or of the absorptive forces for plasma on the endothelial lining cannot be given. Microscopic observation of moving blood in tiny vessels has shown that the red cells congregate in the center of the stream, which is presumptive evidence for a greater axial velocity. Whether we can assume from this that a parabolic flow distribution would be found in the large arterial vessels is open to question. While streamline flow has been described for the aorta (92), there remains some question as to whether a normal flow pattern could be said to have persisted during the measurements, and whether the streaming would apply over the whole cardiac cycle (84).

The large arteries are not rigid, so that any equation relating energy dissipation to tube radius will be complex. Further, the arterial system seldom has any tubes which continue uninterrupted for an appreciable distance. Each vessel has frequent branchings. With the exception of the ascending aorta (44) and the main pulmonary artery (88), with each branching there is an increase in the aggregate cross-sectional area. These junctions appear smooth and tapered, so that the orifice problem is probably at its simplest.

Further, most trunk vessels show a gradual taper through their length. Exceptions to this, that come to mind, are a region of the descending thoracic aorta and one of the carotid artery, which appear to be more nearly true cylinders.

Too detailed a particularization of the various factors which give rise to frictional resistance may be nonessential. The total effect of them all should be measurable by a decrease in mean pressure, over a whole cardiac cycle, from the upper aorta to the peripheral arteries. Several studies have shown that in the aorta such a decrease is so small as to be within the error of measurement (42, 68). In fact, there is no clear loss in mean pressure in man until the brachial or femoral arteries are reached.

Despite this small frictional dissipation of energy attending propagation, there is a very clear difference between the pressure energy developed in systole and in diastole. Except under rare circumstances, the mean systolic pressure is greater than the mean diastolic pressure. This excess of pressure energy could denote an inability of the stretch of the extensible wall to keep pace with the force applied by cardiac ejection, so that energy is stored in potential form in the visco-elastic walls, or it could indicate a different pressure-flow relationship in the large vessels being filled during systole, and that which marks "drainage" through the peripheral arterioles.

To go from generalities to the specifics, an analysis of aortic function could be focused upon three large questions: 1) What are the essential features of the tension-length curves shown by the walls and the derived pressure-volume curves, and to what extent are these curves subject to physiological and pathological change? 2) How does wall distention affect the conduit properties of the vessels? 3) What factors influence the capacity of the arteries to serve as a blood reservoir?

MEASUREMENT OF AORTIC DISTENSIBILITY

General Characteristics of the Tension-Length Curve

Until quite recently, measurements of the extensibility of blood vessels were made on isolated tissues, using two procedures (11, 15, 22, 37, 51, 62, 65-67, 76, 107, 118). Usually a ring (for circular stretching to produce an increase in circumference) or a cut strip (for measuring longitudinal change) was subjected to weight loads, the changes in length being recorded. In a few cases, volume was injected into a

tied-off vessel, recording pressure. Any change in the other dimension, e.g., a longitudinal change during circular stretching, was either inadequately measured or ignored. Although the specific techniques for increasing load have varied, the stretches were made rather slowly so that the vessel could approach, if not attain, a stable length value, i.e., a "static" value. Whether the load was applied in a continuously increasing manner or stepwise, the data were generally presented as a single tension-length curve covering the whole physiological range. All workers agree that such a curve is not linear, but shows a relatively great extensibility at low tension settings and a progressive wall stiffening as the load increases (fig. 1). This curve is therefore different from that shown by metals, even those that obey Hooke's law over the greatest part of their extension, or by rubber, where the length change becomes relatively greater at high tension levels (46). A rubber tube wrapped with a fibrous jacket, such as a garden hose, shows the same type of curve as does the aorta (14). Rings taken from the aorta or from arteries appear to differ only quantitatively. Further, the longitudinal stretch curves are qualitatively similar to those obtained with a circular stretch.

The tension given in figure 1A is the weight load divided by the product of the length of the ring of the thoracic aorta and the wall thickness. This can be converted to internal pressure by dividing by the radius. To express pressure in the usual physiological terms of mm Hg, the obtained value is divided by 13.5. We can calculate the volume per unit length of vessel as πr^2 . Both pressure-diameter and pressure-volume curves show two inflections, to give the curve a somewhat sigmoid appearance (figs. 1B and C). The pressure level at which these inflections are seen varies with different regions of the aorta. Hence both inflections are set at a higher pressure in the upper aorta than in the lower, and the lower inflection may not be seen at all in the arteries (46). There is no simple formula which will fit this sigmoid type of curve, or even that portion of greatest physiological significance. At outset, it is clear that any comparison of vessel distensibility from time to time, or between animals, will require the use of the same arterial region and the same pressure span.

There are several inadequately explained properties of the isolated specimens which seriously affect the recorded extensibility curves. First, as the vessel is dissected out of the body, there is an immediate shortening of its length and a tensing of its walls. This is true whether the animal has just been killed,

FIG. 1. Stretch curves for a ring of thoracic aorta of a dog. In situ length = 10.5 mm. Curves 1 represent the first stretch curve, made by continuous tension increase over 1 min. Curves 2 are the results of a second stretch identical in load and timing to the first. Curves *R* show the curves taken during the gradual release of tension, over 1 min. Curves *C* show the effect of muscle contraction by immersion of the ring in epinephrine.

or has been dead for some time, and whether the voluntary muscles are in a state of rigor mortis or not. The change develops no matter how carefully the removal is done. The interpretation placed upon this change in the past is that it reflects a strong contraction of the smooth muscle contained in the wall. Aside from the speed of its development, which contrasts with the slower time course of muscle contraction, and the lack of correlation between the amount of longitudinal shortening and the proportionate amount of muscle in the wall (ascending aorta, for example, contracts to the greatest degree), there are other features which do not fit too well with this interpretation.

When such a tensed ring is subjected to stretch, and the load is then removed, the walls are no longer so tense, and the circumference is about 30 per cent greater than before the stretch. What was not realized in the earlier studies was that the amount of this diameter increase bears a direct relation to the total stretch imposed (96). Now, if a second stretch of the same size is made, the stretch curve starts from the greater initial value and courses almost parallel to the first through the region of greatest extensibility (fig. 1A). Then, as the wall stiffens, the second curve becomes enough steeper that it merges with the first some time before the peak load is reached. This merging argues against a conclusion that the first stretch had caused some irreparable tissue damage, such as an internal tearing. If, after the first stretch and stretch release is completed, the tissue is allowed

to remain unloaded for a long period (several hours), the original small diameter may be almost, if not fully, restored. If the first stretch had "pulled out" an existing muscle spasm, why should it reform and take so long in doing so? Experiments designed to test this "pulling out" idea with smooth muscle organs, such as the gut, have given little indication that an active contraction itself is eliminated by an extension of the whole tissue under load (6, 101).

With a relatively large load, a third stretch made after the second usually gives a stretch curve identical to that of the second. This fact has been recognized by many past workers who were aware that a large initial stretch, which was not quantitated, made subsequent stretch curves more reproducible. Such reproducibility does not mean that they are necessarily more descriptive of the behavior of the vessel in vivo. With a similar load, successive stretches may start from progressively increasing initial diameters, but a reproducible stretch curve is reached within 5 to 10 stretches. Unfortunately, when examining past studies, it is impossible to be sure whether a preliminary stretch was used, and, if so, how much tension was involved and how long a time interval was allowed before the recorded stretch was made.

The Hysteresis Loop

Until recently, too, little attention was paid to the fact that as the loads were removed the length curve did not follow, during this stretch release, the previous

stretch curve (fig. 1). Hence for any given stretch two different tension-length curves must be considered, one for the extension and the other for the elastic recoil. The difference between the two comprises a hysteresis loop. The amount of hysteresis is always greatest with the first stretch done after a prolonged rest period. If this first stretch is followed by repetitive stretches of the same size, the hysteresis is progressively reduced until it becomes relatively constant. The number of successive stretches required to achieve this stable loop varies among vessels, for two or three stretches will suffice with the aorta, but more may be needed with a muscular artery. In the gradual reduction of hysteresis, the stretch-release curve remains almost or completely constant, its values being set by the peak load used (96). It is the extension curve which shows progressively larger length values at any given tension value. Hysteresis is present in some metals, too, although its amount is relatively small as compared to that seen with vascular tissues.

The presence of hysteresis is often taken to indicate simply a viscous retardation of the extension of elastic elements, and handled in formulas as though it were simple viscosity (48). This would mean that the size of the loop is an index to the frictional energy dissipation, which, in turn, would be directly related to the rate of the imposed stretch. Hysteresis of the vessel wall is not so easily formulated. We can summarize its main features by saying that at least three factors seem involved.

1) While a viscous retardation is present, it can be demonstrated for the aorta only at very rapid rates of stretch (96). A rate dependency has not been seen for the stretch-release curve. The muscular arteries have more rate-dependent hysteresis than does the aorta.

2) When a stretched length is held constant for a period of time, some internal elongation of elements still continues, so that the tension falls. This decline is called stress relaxation. Or if a tension value is maintained, the length will continue to increase slowly, which process is known as "creep." The amount of creep is a function of time, but the relation is not easily formulated in quantitative terms.

Muscle physiologists have frequently referred to this slow continued elongation under stress as plasticity (13, 93). This use of the term "plastic" is not very appropriate. With metals, when an applied increasing stress reaches a certain critical value, the material becomes deformed. The length change accompanying this deformation may show the properties of viscosity, but the term plastic does not denote the presence or

absence of such viscosity. Once deformed, the material does not return to the original length upon removal of the stress, but retains the increased length. The choice of the word plasticity for the slow elongation of muscle lay with the belief that any reversibility could be brought about only by an active muscle contraction. However, the process which underlies stress relaxation is spontaneously and completely reversible, if enough time is allowed, whether the muscle is alive or dead (101). Muscle contraction may, of course, hasten the return to the original length. Stress relaxation involves a complicated type of internal viscosity which is so arranged that the driving force for length return lies with some parallel elastic unit which is under stretch.

Just as with rate-dependent viscosity, the stress-relaxation component is but a minor part of hysteresis as seen in the aorta (96). Its influence is more evident the longer the vessel is kept at a peak load, or the longer the vessel remains under no load, so that creep recovery, or the reversible phase of stress relaxation, can continue.

3) When, with successive stretches, a final "stable hysteresis loop" is obtained, neither the values from the stretch phase nor those from the release phase show any dependency upon the rate of stretch, and a dependence upon time cannot be easily described. For want of a better term for the remaining factor, which seems to dictate the greatest part of the hysteresis behavior, I have called it simply an architectural rearrangement. The change is certainly dependent upon the amount of stress and involves a reversible change in length. While there must be some time dimension to this internal rearrangement, the change presumably is very rapid. It may be at a molecular level or at a tissue fiber level.

What should be firmly emphasized is that a tissue probably has a great many different viscous elements with different time constants. When we refer to such a tissue as being visco-elastic, it does not mean that all the different viscosities can be lumped to give a single viscosity, with an easily definable rate dependency.

In view of the complexities that influence a tension-length curve, it is possible that we should think of the firming of the aortic wall, upon removal from the body, in terms quite different from that of a muscle contraction. The vessel is held in situ under considerable longitudinal restraint (104, 107). When a segment is cut, elastic elements held lengthwise under stretch should recoil and make the wall thicker. When, with a circular stretch, no attempt is made to restore

the original length, there could be a reorientation of these elements into the circular plane, leaving a ring with a larger circumference. This indicates, as is probable, that both longitudinal and circular elastic elements are part of a linked network, and therefore not independent. In our studies on isolated rings, when we converted the actual tension-length values to pressures and volume, we used *in situ* length rather than the actual one. This mathematical step was better than using the actual lengths, but is not necessarily sufficient as a correction if elements previously oriented longitudinally were participating in the circular stretch.

This is not to say that all the hysteresis phenomenon could be due to a progressive recruitment of longitudinal fibers into a circular plane. The loop still present, despite many consecutive stretchings, probably denotes a structural rearrangement of elements under load that were already in the plane of the stretch. It is admittedly strange that such a rearrangement would have no clear time dimension.

An occluded, *in situ* aorta being pulsed by volume injections shows a similar pattern of hysteresis and change in extensibility curve with successive stretches (5). We attempted a quantitative assessment of possible differences between total aortic distensibility, as measured by injections of saline into dead but *in situ* aortas, and as compiled from stretch data made on rings cut serially from the same vessels (103). The volume required to produce a given rise in pressure was greater than that estimated from the first stretch curves of the isolated rings. It was also a little greater, although perhaps not significantly so, than that expected from the second stretch curves.

On hindsight, this comparison may not have been so definitive as we supposed. At the time the experiments were done, we were not so aware of the large effect of the time interval between successive stretches, of the initial pressure level, and of the peak pressure reached, on the contour and values of the extension curve.

Selection of Representative Curves

Historically, an interpretation of vessel wall architecture has been based on the contour of a first, or a second, large and continuous extension curve. It should now be obvious that this contour should not be regarded as characteristic of wall extension during unceasing, repetitive stretches, such as would be present during life. How large the differences between the two curves might be will be elaborated more

fully later in this paper. Ultimately, a study of vessel wall behavior must be based on pressure and diameter or volume measurements made during life. Such studies will be technically difficult, and interpretation of the records will be difficult, since in life the heart rate and the pulse pressure are continually changing from beat to beat. Work on this problem is in progress in a number of laboratories, and some results have been published (87, 91, 113). Unfortunately, these show some differences, and the adequacy of the various techniques has yet to be firmly established. But taking the data as they now stand, it appears possible that while the amount of hysteresis varies among arteries, it is probably less than that shown by the isolated rings. This may be because the living aorta is being cyclically stretched without pause.

The suggestion, which needs further corroboration, that the diameter change of a living vessel for a given pulse pressure is less than that given by an isolated ring (61, 78, 87, 91) could indicate that, for some quite unknown reason, a very different distensibility is present in the living vessel. In one study (91) the reported diameter change is so much smaller that our whole concept of the functional character of the vessel, as will be developed in this paper, would have to be changed. We are not satisfied yet that the instrument used could record a change as large as that expected from the ring stretch data. Reconciliation between the various sets of data should not be long delayed.

Until the properties of the *in vivo* aorta are known more surely, we must base a description of the factors which might condition the extensibility curve on data taken from isolated rings. If these data should eventually prove quantitatively wrong, we can only hope that the fundamental properties of the vessel would nonetheless be qualitatively the same. First, the nonlinearity of the continuous stretch curve is evidence for an internal architecture more complicated than that seen even with rubber or other polymers. In the range of maximal extensibility, the aorta shows more length change per unit tension increase than any other material of comparable wall thickness. Nature seems to have created a far better volume reservoir than man can duplicate.

Histological Considerations

We know from histological evidence that the large vessels have four general types of tissue—endothelial cells (with associated intracellular materials), smooth muscle cells, elastic fibers, and collagenous fibers. Because histology texts tend to emphasize a collection

of these tissues into more or less well-demarcated layers, physiologists have taken what probably is an oversimplified approach to an analysis of wall extensibility, and have considered each of these tissue types to be unconnected and arranged in parallel. But while elastic tissue does appear to be condensed into layers, it also is interspersed between muscle and collagenous fibers. And there seem to be connections between the gross layers themselves, which means that we can hardly consider the influence of any one tissue type alone. Nor are we at all certain about the elastic characteristics of the different tissues, even if they were to behave independently. The extensibility of the endothelial cells is relatively unknown in any quantitative sense. Since they comprise but a very small part of the wall, and since they certainly are not stiff enough that they are torn by even large stretches, they probably are relatively extensible, and their influence can probably be neglected for the present. An estimate of the extensibility of collagenous fibers has been taken from that shown by tendon, although the collagenous fibers of the latter are larger and more densely packed. As opposed to a tissue containing elastic fibers, tendon is quite inextensible and shows a linear stress-strain relation with no discernible visco-elastic properties (21, 52, 67, 97, 103, 112). The aortic wall stiffening seen when the pressure rises above about 100 mm Hg has thus been attributed to the resistance to stretch offered by the enclosing jacket of collagenous fibers (21, 103). Aortic walls from which elastic tissue and muscle have been digested show a similar stiff wall (50, 111). This jacket must fit loosely and be considered in parallel to the underlying elastic tissue. Once it starts to participate in the stretch, it will assume the bulk of the applied load.

On the basis of stretch curves shown by ligamentum nuchae, which is predominantly elastic tissue, elastic fibers are much more extensible than collagenous fibers. Chemically treated aortas which retain only their elastin show an increased extensibility, one not greatly different from that of the whole vessel in the lower stretch range (51, 52, 74, 111). Most workers ascribe a linear stress-strain relation to these fibers, too. Hence my work (97) seems to stand alone in the claim that ligamentum nuchae shows a nonlinear curve not unlike that of the arteries (with a stiffening in the upper tension range despite the absence of any clear collagenous fibrous coat), and also has visco-elastic properties similar to those of the aorta. Since the elastic fibers in both organs seem arranged in a reticulum, and since the visco-elastic properties of

dog ligamentum nuchae seem clear, the following analysis will be based on a similarity in stretch behavior of the two tissues.

Assessment of the extensibility of smooth muscle cells is on most insecure ground. Studies have been made of the stretch properties of muscular organs, such as the bladder or gut, for this purpose (6, 97, 101, 102), although the muscle fibers here are enmeshed in a loose weave of collagenous and even some elastic fibers too. If this muscular tissue is subjected to a moderately rapid stretch, its extensibility is only about a third as great as that shown by ligamentum nuchae (97). But because these tissues have such a pronounced time-dependent creep, if one waits for the length to approach a final value under a given load, the total extensibility is greater than that of elastic tissue. This has been the procedure used when elastic moduli for muscular structures have been derived. But it seems unreasonable that the muscle contained in the aortic wall could show such a prolonged creep. If the muscle cells are coupled to the elastic fibers, creep would be effectively prevented by the resistance these fibers would offer to an elongation. Of course, the greater the amount of muscle involved in the vessel wall, the greater would be the creep. At one extreme, the umbilical artery, which is almost solely muscle, shows a very pronounced stress relaxation under load (122, 141). In most large arterial vessels the relaxation is of more limited degree. Hence the muscle contained would probably be stiffer than the elastic fibers, which would remain the most extensible part of the wall.

It should be noted that the pulmonary artery shows a difference in distensibility behavior from the aorta. The form of the stretch curve is more akin to that of a large vein (105). The vessel shows more creep than does the aorta (32). The form and the total length change of the stretch curve are different in pulmonary vessels that have been frozen and thawed than when simply kept in Ringer-Tyrode solution (a reflection of the effect of viable muscle?) (32).

There is histological evidence that, in the aortic wall at least, muscle cells, elastic fibers, and some collagenous fibers are interlinked into a three-dimensional network (11, 109). The elements in this network could be partly in series and partly in parallel. The extensibility of the whole tissue could be a reflection of the form of the net just as well as it could be conditioned by the individual tissues. For example, Bull (20) showed that while a single nylon thread obeyed Hooke's law, and had no visco-elastic behavior, a stocking woven from such a thread

showed a bowed extensibility curve not unlike that of the aorta or of ligamentum nuchae, and also showed a pronounced hysteresis loop. When I stretched a stocking by the techniques used for an isolated ring of aorta, the dry specimen showed an appreciable rate-dependent element (viscosity) in the tension response to a given strain. When the stocking was wet, this viscous element was relatively reduced, and there was unmasked both a prolonged creep and the "architectural dependency" which is so conspicuous for the hysteresis behavior of the aorta.

If the analogy of the stocking is valid, the first part of the stretch curve of the aorta would reflect only a geometrical rearrangement of the net. The resistance to stretch would be a function of the looseness of the "weave" and the presence of a lubricant (as in the wet stocking); there also could be a "set" of the net, which could be subject to change with time, with muscular activity, and, very definitely, be influenced by the size of a previous stretch. When, under applied load, the net lost its form, the extensibility would progressively decrease, both because the mechanical advantage of the fibers in resisting the stretch would be increased and because the fibers themselves would now be involved in the extension. If our ideas of the relative extensibilities of the different components is correct, and if they were arranged in the net in series, the elastic fibers, being most extensible, would condition the extension of the whole wall. With more load, these elastic fibers would become stiffer (as they do in ligamentum nuchae), and other components of the net could be increasingly involved. Probably the idea of a parallel outer collagenous jacket should still be retained to contribute to the final wall stiffness.

In an earlier analysis (103) we treated the aorta as though it contained the three tissue types as arranged in parallel. Since muscle had to be able to reduce the vessel diameter below its normal unloaded size, we conceived of the elastic jacket as fitting loosely over the muscle coat. This would mean that muscle alone would be involved in the very first part of the stretch curve, and that only later in the stretch would the elastic fibers start to participate. Such an arrangement seemed amply supported by evidence obtained with stretchings repeated daily, using rings as they were allowed to putrefy. In this process muscle cells lost their integrity first and the unloaded diameter increased while the initial slope of the stretch curve became steeper. Much later, the elastic fibers softened and their continuity became disrupted. Now the unloaded diameter had again increased, and the aorta

showed a stiffness not unlike that seen at high load levels in the normal state, which was attributed to the collagenous fibers still present. The net model would fit these putrefaction studies equally well, for loss of muscle could partly disrupt the net to give an increase in unloaded diameter and, at the same time, leave the wall less extensible.

There still remain several features of the viscoelastic behavior of the aortic wall which would not be easily explained on the basis of the net. And the details of net construction are left purposefully vague. The general concept has much in common with the model proposed by Burton (21), except for its de-emphasis of the specific location and role of the muscle fibers themselves. He was much concerned that the muscle be afforded a great mechanical advantage, so that it could always effect a diameter change. Hence he placed these fibers across the plane of a fibrous net, which would protect them from elongation. In muscular tissues it remains uncertain that the contractile ability of muscle fibers is necessarily impaired when they are elongated, even by the amount that may normally be developed in an organ such as the urinary bladder. Further, it may be that even in smooth muscle organs the muscle cells are arranged into a somewhat similar net (101, 102). It may be that the muscles in the aortic wall are attached to adjacent loops of the net (which would give them more of a parallel arrangement than a series one with the elastic and collagenous fibers), so that they could, by shortening, act to "open the weave," and perhaps increase its "set." This need not mean that the stiffer muscle would now condition the extensibility curve, for we could have, with extension, a warping of the net toward these muscle links. Hence, the internal architecture could be quite different when muscle was contracted than when relaxed, even though the diameter values under a given load might be the same.

Effects of Active Muscular Contraction on Distensibility

Whether it is necessary that a model provide muscle with a large mechanical advantage cannot be answered. We are not sure just how effective muscle contraction really is in a vessel under a load equivalent to that of the usual physiological pressure values. Much work is currently being done in which strips of aorta are used as conveniently long tissues to test the effect of drugs, or changed electrolyte environment, on muscle contraction (35, 79, 80, 121). To be useful as a bio-assay material, such strips must be

under minimal load. Isolated aortic rings will, when unloaded, respond to immersion in epinephrine, for example, by a shortening of both their diameter and length, to produce a pressure rise of some 3 to 5 mm Hg. But if these contracted rings are subjected to stretch, the decreased diameter is lost rather early (fig. 1A), so that by the time loads equivalent to the usual working pressures are reached, the contracted and relaxed rings show identical extensibility curves. With stretch release, the diameter does not return to the contracted size. Either the muscle loses its contraction early in the stretch, or the other parts of the net have contributed more than usual to the total extension. Even in muscular organs, such as the bladder (102), the effect of contraction on the extensibility curve is small, and the contraction itself seems not to be eliminated by the imposed stretch (97, 118). The extensibility of a muscular organ is not very different in the contracted or relaxed state (6, 13).

What is more disquieting is that if an aortic ring is first subjected to a load equivalent to a pressure in the usual physiological range, immersion in epinephrine will no longer produce a discernible diameter or pressure change. It is hard to accept this finding as rational. Yet neither viable isolated specimens nor a temporarily occluded aorta *in situ* (5) has been shown to have a more powerful muscle action. This is not to say that a contraction in muscular arteries, where the ratio of wall muscle to internal diameter is greater, could not influence the diameter at the higher pressure levels.

Attempts have been made to record the effects of muscle contraction in the intact aorta while it is being pulsed by the heart. Most of these I have learned of through conversations, since there is reluctance toward publication of negative findings. In the literature are the older experiments of Wiggers & Wegria (138) in which an aortograph was placed around the thoracic aorta of a dog. After an intravenous injection of epinephrine or elicitation of a strong pressor reflex, there was a recorded decrease in diameter (the actual values not being given) at a time when the aortic pressure was not changing. For many years these results stood unchallenged and yet unsupported. More recently, Patel and co-workers (88) found a change in both diameter and wall stiffness in the main pulmonary artery with muscle contraction, a change persisting through several normal pulsations. The pulmonary pressure is, of course, much lower than that of the aorta and the wall architecture is not the same. Then Peterson and

co-workers (91) showed a change in diameter and an increased stiffness, with arterial pressure unaltered, when the femoral artery or carotid artery was painted with norepinephrine. Opposite results were obtained with acetylcholine. The authors claim a similar directional change, but furnish no supporting figures, for the aorta. These results, and particularly the claim for the aorta, must be amplified and confirmed.

Diameter and extensibility changes in the aorta of living animals following the use of constrictor or dilator drugs have been recorded (78) which do not appear to fit with the stretch data obtained with isolated rings. Since the arterial pressure also changed, and since the physiological distensibility curve for the intact aorta, quite aside from any muscle action, remains to be formulated, an attempt to interpret these changes on the basis of muscle contraction would be premature.

We are not yet in a position, then, to answer the long-debated question as to whether muscle contraction should increase or decrease the wall extensibility. The effects of such contraction on the stretch curves shown by isolated vessels are difficult to phrase in terms of generalities. With an unloaded vessel, contraction is not followed by relaxation. Instead, over a period of time, the wall gradually becomes stiffer, as though the fibers had been reset to the shorter length. Whether the contraction had any essential role in this resetting, aside from the first reduction in length, remains uncertain. Depending upon the amount of this resetting, a small stretch, starting from zero tension, will reflect this initial stiffness of the wall. With more stretch, the distensibility suddenly increases, so that the stretch curves of the once contracted and the relaxed ring are now parallel. At higher loads the two curves merge. If one assays distensibility, it must always be with respect to the amount of load used. Thus, if the stretch is sufficient to cause the shift toward the increased distensibility, one would conclude that the muscle contraction had rendered the wall more extensible. If the assay were on the basis of the very first part of the stretch curve only, one would reach the opposite conclusion of a lessened extensibility. Whether the effects shown by an unloaded tissue have any pertinence to what might happen at physiological pressure levels remains to be shown. If, for some reason, the muscle in the living aorta were more powerful, or if the imposed stretch were made quite small, we might anticipate a decreased wall distensibility. Even so, any interpretation of the effect of muscle contraction would have to be phrased in

terms of the shape of the stretch curve, and the total stretch employed.

Effects of Aging on Arterial Distensibility

The effects of aging on arterial distensibility are supposed to be well established—at least the textbooks so report. The actual evidence leaves much to be desired. On the one hand is the story of pathologists that aging is accompanied by a reduction in muscle mass and in elastic tissue, with a replacement by collagenous fibers. The reduction of muscle mass needs documentation by actual cell counts. Chemical digestion of the aortic walls, to leave only elastin, left Lansing (74) unwilling to accept the dictum that the elastic fibers had been reduced in number with age. He would, of course, accept the possibility of a chemical change which might influence the wall extensibility.

Extensibility studies made on isolated vessels taken from humans of different ages suffer from our uncertainty about how to compare extensibility among different specimens. The repeatedly quoted studies of Hallock & Benson (37), based on a small series, in which only the average results of a given age group were presented, showed some decrease in extensibility with age, with the only truly large change seen in individuals over 70 years. The comparative data were expressed in terms of an elastic modulus ($\Delta P/(\Delta l/l)$). Here, as in all other reports (10, 62, 66, 81, 107, 127), there was a progressive increase in unloaded diameter with age, which in itself could increase the value of this modulus. In a study of a larger series of human aortas (107) we presented results taken from the second of two consecutive stretch curves. Variations within the age groups were large. While the group averages showed a progressive increase in initial diameter, it was also true that a man of 68 showed the same diameter as a girl of 18. All these aortas were screened so as to include none showing atherosclerosis, and any from individuals with a history of hypertension were placed in a separate category. The diameter increase was especially noticeable in these hypertensives. The slopes ($\Delta P/\Delta l$) given by the stretch curves also showed intraindividual variation, but they were very much more constant than were the initial diameters, and there was no clear trend for this slope to change with age. A changed modulus value with aging was, then, predominantly conditioned by a change in the initial diameter.

Expression of Extensibility in Terms of Moduli

This raises the question as to just how meaningful a modulus value is in expressing extensibility data. Certainly having to present a whole stretch curve for each specimen studied is cumbersome, and such data are difficult to handle statistically. But a modulus is supposed to afford insight into the architecture of the specimen. Thus when a physicist wishes to describe the extensibility as a property of a material, he uses Young's modulus, or a related one, which is simply the ratio of the applied extending force or stress, as expressed per unit area of material, to the proportionate change in length from the unloaded value. Most of his materials are so stiff that the strain is small. Further, the material promptly returns to the initial length upon removal of the stress, and in measuring extensibility he obtains a clue to the force of this return. He therefore calls his modulus one of elasticity, despite the fact that he is measuring extensibility and not elasticity at all. Any time delay in effecting the strain is usually so brief as to be inconsequential. When the ratio of stress to proportional strain is constant (he carefully avoids a load sufficient to cause permanent yield or plastic deformation), this ratio can be calculated by using any convenient load. Because most materials do not have a constant ratio, and some, as cast iron, depart quite significantly from a linear relation, he tries to make his applied stress as small as feasible.

When we turn to materials such as the polymers, the stress-to-strain ratio is definitely not linear. Further, the recorded strain is a function of the time allowed under load; and the material may not promptly return to the same unloaded length. Because of the last, it is definitely not proper to call the modulus one of elasticity. As a substitute, one could construct a modulus of extensibility, which would be the reciprocal of what is usually called the modulus of elasticity. On the thesis that there has been no internal change in the material because of the stress, and that the original internal architecture will be precisely restored after load release, the physicist continues to use a modulus as a proper expression of extensibility even with polymers. To emphasize the fact that the modulus calculations are based only on the values seen during extension, rather than during the elastic recoil, I have used the symbol S rather than the conventional E in all the equations presented below. It should be obvious that one must append to any modulus calculation a careful descrip-

tion of the stress used and the time over which it acted. This has seldom been done. A derived slope obtained by the use of a conveniently large stress, because of the nonlinearity of the stretch curve, often has no counterpart in this curve—the modulus represents a mathematical figure only.

Evidence presented above leaves room for doubt that the internal structure of a vascular tissue is necessarily the same, just because the unloaded diameter might be restored. This restoration might involve muscle contraction, or it might be due to a passive creep recovery. Even in the latter case, an architectural rearrangement conditioned by the stretch might still be present. We have seen that, with enough load, the contracted ring may start from a smaller diameter but reach the same stretched value as an unstimulated one. Shall we, from the calculated modulus value, deduce that the tissue has been weakened because of the muscle contraction? We have seen that with aging the unloaded diameter tends to increase—an increase which may or may not be at the expense of the elements which condition the major portion of wall extensibility. Here, a calculated modulus value might seem to be evidence for a wall stiffening, which may or may not have developed. In those cases where the slope of the pressure-volume curve remains unchanged, we may seriously doubt that the increased modulus value is an overly meaningful index to wall stiffness.

The claim is often made that the increase in diameter is a way of compensating for a wall stiffening with age. This statement arose from the modulus formula itself. If the ratio of $\Delta P/\Delta l$ remains constant, the volume uptake for a unit length of vessel remains constant, and the change in initial diameter can hardly be said to be a compensation at all. Actually, as will be discussed later, the diameter change will affect the propagation velocity of the pulse wave, which will affect the length of vessel that is receiving volume at any given time interval. Thus, indirectly, some compensation for a wall stiffening might be effected, but it is questionable that this effect can be stated in quantitative terms, and any such formulation certainly would not use the same equation as is used for a modulus calculation. For the time being, it appears essential that before we can talk in meaningful fashion about changes in stiffness of the wall, a change in the actual slope of the pressure-diameter or pressure-volume curve alone must be shown. It is on this last point that the evidence on the effect of aging seems to be weakest.

Since, when one is working with a vessel during life, the stretch does not start from an unloaded size, another modulus has often been substituted, in which the diameter change is related to the real size seen just before the new increment in stress was applied, i.e., the diastolic diameter. This modulus is just as justifiable as that given above, but its value must be quite different. One can be converted to the other arithmetically only if the tension-length relation is linear. Unfortunately, the two moduli have too often been treated as interchangeable. Finally, since changes in pressure and volume are usually the primary data in the living aorta, a modulus based on the pressure-volume relation has been substituted. Conversion of this modulus to that using tension and length is quite complicated. Perhaps the interrelations could be best expressed in terms of their derivations:

Young's modulus (length) is the applied force per unit area divided by the proportionate length change. For a circumference increase, the area over which a given load is applied will be the length of the ring (l) times the wall thickness (a). The strain will then be the relative increase in circumference, i.e., $2\pi\Delta r/2\pi r$, or $\Delta r/r$. Since the material is being stretched from an unloaded state, the applied tension will be ΔT , and r will be r_0 .

Thus

$$S_0 = \frac{\Delta T}{\frac{\Delta r}{r_0}} = \frac{\Delta T r_0}{\Delta r} \quad (1)$$

If the change in radius and in tension are small enough that they lie on the actual stretch curve, the equation can be written as

$$S_0 = \frac{dT r_0}{dr} \quad (2)$$

This derivation assumes that there will be no significant change in length or in wall thickness accompanying the radial stretch, which, with large diameter changes at least, is certainly not true, as will be discussed later.

Now let us suppose that the initial radius is not the unloaded value, but is taken when the tissue is already under stretch. The basic equation would not be altered:

$$S_d = \frac{\Delta T r_d}{\Delta r} \quad (3)$$

but the value for S_d would not be the same as that for S_o . If the changes are very small,

$$S_d = \frac{dT r_d}{dr} \quad (4)$$

Next, let us express the stress in terms of pressure. This is usually done by taking the pressure (P) as equal to T/r (21). As pointed out by Frank (29), and stressed recently by Peterson *et al.* (91), when the wall is relatively thick in relation to the internal radius, the more proper expression would be $P = Ta/r$, where a is wall thickness. With an imposed stretch: $P + \Delta P = a(T + \Delta T)/(r + \Delta r)$. When $P = 0$ and $T = 0$, this becomes $\Delta P(r_o + \Delta r)/a = \Delta T$. Substituting for ΔT in equation 1:

$$S_o = \frac{\Delta P(r_o + \Delta r)r_o}{a \Delta r} \quad (5)$$

If Δr and ΔP are very small, their product will be infinitesimal, so that

$$S_o = \frac{dPr_o^2}{a dr} \quad (6)$$

And from equations 3 and 4 we obtain:

$$S_d = \frac{\Delta P(r_d + \Delta r)r_d}{a \Delta r} \quad (7)$$

and

$$S_d = \frac{dPr_d^2}{a dr} \quad (8)$$

Now to express the radius change in terms of volume:

$$\begin{aligned} V &= l\pi r^2, \text{ and } V + \Delta V = l\pi(r + \Delta r)^2 \\ &= l\pi(r^2 + 2r\Delta r + \Delta r^2), \text{ or} \\ \Delta V &= l\pi(2r\Delta r + \Delta r^2), \text{ or} \\ \Delta r &= \frac{\Delta V}{l\pi(2r + \Delta r)} \end{aligned}$$

Substituting for Δr in the denominator and then for $l\pi r^2$ in the numerator of equation 5:

$$\begin{aligned} S_o &= \frac{\Delta P(r_o + \Delta r)r_o l\pi(2r_o + \Delta r)}{a \Delta V} \\ &= \frac{\Delta P(2l\pi r_o^3 + 3l\pi r_o^2 \Delta r + l\pi r_o \Delta r^2)}{a \Delta V} \\ &= \frac{\Delta P(2V_o r_o + 3V_o \Delta r + \frac{V_o \Delta r^2}{r_o})}{a \Delta V} \\ &= \frac{\Delta PV_o(2r_o + 3\Delta r + \frac{\Delta r^2}{r_o})}{a \Delta V} \end{aligned} \quad (9)$$

and

$$S_o = \frac{2dPV_o r_o}{a dV} \quad (10)$$

Substituting for Δr in the denominator of equation 7, and following through as in equations 9 and 10:

$$\begin{aligned} S_d &= \frac{\Delta P(r_d + \Delta r)r_d l\pi(2r_d + \Delta r)}{a \Delta V} \\ &= \frac{\Delta PV_d(2r_d + 3\Delta r + \frac{\Delta r^2}{r_d})}{a \Delta V} \end{aligned} \quad (11)$$

and

$$S_d = \frac{2dPV_d r_d}{a dV} \quad (12)$$

A commonly used, but incomplete, modulus (see equation 7) is:

$$S_d' = \frac{\Delta P r_d}{\Delta r} \quad (13)$$

And another (see equation 11) is:

$$S_d'' = \frac{\Delta PV_d}{\Delta V} \quad (14)$$

The relationship between these moduli could be illustrated by taking a hypothetical tube with an unloaded radius of 10 mm, in which the radius increased 1 mm for each 1 g per cm² increase in tension. The stress-strain relation will then be as shown in figure 2A. The value for the modulus (equation 1) would be 10. The calculated pressure-radius and pressure-volume curves would not be linear (fig. 2B and C).

A modulus calculated on the basis of a loaded initial radius (equation 3) will increase as r_d increases (table 1). A modulus based on pressure change would give the constant value of 10 if equation 5 is used, but if equation 6 is employed, the S_o value decreases as the strain becomes larger, so that even a 1 per cent change in strain produces a decreased value. Curiously enough, the value of S_d calculated from equation 7 shows a constant value, while that from equation 8 progressively decreases.

Converting the radius changes to volume increases makes the formulas very cumbersome. Once again, equation 10 gives a changing modulus for S_o , as does equation 12 for S_d . There is no simple way of converting the moduli values obtained from the different formulas to each other.

Based on studies with rubber, King (62, 63) introduced another measure of extensibility, β , which is the ratio of the unstretched length L_o to the maxi-

FIG. 2. Extensibility and derived distensibility relations for a hypothetical tube showing a linear tension-length relationship.

imum extension possible. Hence $\beta = L_o'/(L_{\max} - L_o)$. If a proper L_{\max} can be determined, this ratio has several advantages, but it also suffers from the same uncertainty as to what a proper L_o value should be, particularly if, in constructing the relationship, the tissue has been stretched so as to approach L_{\max} .

It has become common to compare a "dynamic" modulus, as obtained with rapidly repeated small stretches, to a "static" modulus. For example, Lawton (77) and Cope (22) reported a small increase in the dynamic value over the static for the aorta, which presumably reflects the influence of the rate-dependent factors involved in the visco-elastic behavior. But there is confusion as to how a static value should be determined. Sometimes values taken from a single continuous stretch curve covering the whole range of physiological pressures are used if the involved stretch has been done slowly. In other cases, a pressure-length value representing the center of the dynamic loop is taken as indicating the static value. Only rarely does this give a value different from one based on the peak values of the loop, and it would appear to strain the definition to take this as a static value at all. A third method is to hold a peak load constant until, through creep, the length has approached a final value. All three methods give different values, which simply indicates again that more than viscosity is concerned in tissue hysteresis. This can be illustrated by an experiment shown in figure 3. An isolated ring of dog thoracic aorta was first subjected to a continuously increasing stretch,

over 2 min, to a high tension. Tension was converted to pressure, and half-circumference to volume. The peak tension thus represented a pressure of 350 mm Hg. The load was then slowly released, over 2 min, and, as before, the ring did not return to the same initial volume setting. A second identical stretch (in terms of tension) was then made. The relations obtained during this second stretch and stretch release are plotted as the solid line in the figure. This stretch curve is not different from those we have used in the past to classify the distensibility of aortic rings. Now the ring was allowed to remain in Locke-Ringer's solution for 2 hours, during which time the unloaded volume was very slowly decreased. It was mounted on the stretching apparatus, care being taken not to stretch it in the process. A small length change was then made rather rapidly (0.1 sec), and the stretch repeated in rapid succession ten times. Stable stretch and stretch-release curves were established by this time. The pressure-volume relations of this stable loop are given in the figure as loop A. The same stretch was then performed an 11th time, but the peak value was held constant for 5 min, allowing the pressure to fall to its static value, some 2 mm Hg lower. The ring was then returned to a volume setting part way up the original loop, and a new series of rapid stretches made, the last loop being shown as B in figure 3. Again a static pressure was obtained. The whole process was repeated 13 times.

The initial volume for the loops was first smaller

FIG. 3. Pressure-volume relations for a ring of dog thoracic aorta, in situ length 10 mm, with stretch done by continuous stretch (curve *S*) and by successive, repeated dynamic stretches. The broken line, curve *R*, is the stretch-release curve for the continuous stretch. The crosses mark the mid points of the successive hysteresis loops. The solid points represent the postdecay (static) tension values reached 5 min after completion of the stretch.

than that given by the continuous curve, but crossed it and became greater at high pressure levels. The continuous curve reflected the large stretch which had preceded it. If less load had been used for this stretch, the curve would have differed less at low pressure settings, but even more at high pressures. It might seem that a pressure-volume curve obtained by joining the midpoints of the respective loops might give a better measure of aortic distensibility. But, in life, the aorta is never free from stretches, and any departure from normotensive pressure levels is but temporary. We would expect, then, that when the pressure did fall below normal, the aortic volume would be greater than indicated by this curve constructed from the loops.

More important, the volume change (ΔV) for the different pulse pressures was almost the same for the different loops as when taken from the continuous curve. This is particularly true in the normotensive pressure range. Hence, the very different methods of stretching produced some, but not large, changes in the $\Delta P/\Delta V$ value. Now let us express these distensibility curves in terms of moduli, using equation 14. As shown in figure 4, the dynamic S_d for each of the loops, using the peak value only, was greater than

the static by an average of 10 per cent. The continuous stretch curve gave modulus values varying from -15 to $+12$ per cent of the static, with an average difference of $+2$ per cent. Also shown in figure 4 are the modulus values calculated for only the very first part of the stretch curve for each of the loops. The fit with the other moduli is erratic, but the values are considerably greater than those based on peak values. These results are given in detail only to illustrate how difficult it is to classify the behavior of the aorta on the basis of any single technique of performing stretches.

Changes in Length and Wall Thickness of Arteries

In all modulus calculations, it is unrealistically assumed that length and wall thickness remain constant. Lawton (76) presented evidence that the volume of the aortic wall remained unchanged during a stretch. This means that as the circumference increases, there should be either a shortening in length or a decrease in thickness. Fenn (26) and Fawcett calculated that if the wall is isotropic, there should be no length change, so that only wall thickness would be involved. A direct recording of the

FIG. 4. Distensibility modulus (eq. 14) calculated from the data of fig. 3. Solid line, from continuous stretch curve. Dotted line with dots, from peak values for hysteresis loops. Dotted line with triangles, from postdecay (static) values for loops. Broken line, from initial slopes of stretch curves of hysteresis loops.

change in thickness during a stretch has not been made. There are some sparse references to the relation of the unloaded thickness (a) to the outside diameter (D). Thus King (62) found an a/D ratio of .09 for human aortas. McDonald (84), in a survey of many arteries from the dog, found a constant ratio of .08. In studying the effect of age on the human aorta, King (64) found a progressive decrease in thickness, so that the product of thickness and radius was nearly constant. On the other hand, young aortas show more longitudinal retraction upon excision than do those from older people (107), which might account for part, at least, of the difference in wall thickness. The question of how much the wall thins during a stretch needs documentation, since this factor will affect the derived modulus value.

In isolated vessels subjected to a volume increase, Fenn found a lengthening, from which he concluded that the wall was anisotropic (26). McDonald (84) is quite correct in emphasizing that the longitudinal extensibility observed in isolated vessels may not be a measure of changes that might take place in the in situ vessel under longitudinal restraint. Hence if the intact vessel is in the steep portion of the longi-

tudinal extensibility curve, its length changes with each pulse would not be large. The presence of the aortic sheath might also reduce length change in the in situ aorta. It is of interest here that a pulmonary artery freed from surrounding connective tissue showed a longitudinal thrust with a volume injection, while one still bound showed but minor change (32). Yet the vessel wall should not become anisotropic simply because it was released from its longitudinal restraint. Length changes in living animals have not been completely measured. Lawton (78), working with serial photographs of a dog abdominal aorta, found a small shortening in early systole and a lengthening in diastole. This made the length and circumference changes almost 180 degrees out of phase. Similar length changes for the abdominal aorta were found by Patel and co-workers (87). In contrast, they found length and diameter changes to be in phase in the thoracic aorta.

The small length changes recorded seem in sharp contrast to the sometimes rather striking longitudinal thrusts seen in the aortic arch. And at times a freed carotid artery, or more rarely a femoral artery, visually seems to be showing a length change. These thrusts might reflect factors other than a distention upon invasion by the pulse wave, however. The heart is anchored in the chest by the large vessels. It has long been known that the base of the heart is lowered in contraction, which must serve to lengthen the aorta and pulmonary artery (47). Rushmer (113) has described this movement as starting in the period of isometric contraction. The motion of the arch, and of the brachiocephalic arteries which serve as anchor points for the arch, would reflect not only the geometry of the vessels but the firmness of attachment of the descending arch to the body wall. Further, respiration displaces the aorta, which acts as though it is bound rather firmly to the diaphragm. These longitudinal thrusts would bear no necessary time relation to the arrival of the pulse wave, and a deciphering of the origin of length changes in a vessel may not be easy.

Considerable confusion was raised by a report (113) that when diameter and pressure were simultaneously recorded in the thoracic aorta, an unorthodox hysteresis loop was obtained in which, during stretch, the diameter change was proportionately greater than the pressure change. These loops were taken from an oscilloscope. Inspection of the individual diameter and pressure records indicates that the whole of the diameter curve simply preceded the pressure curve (126). If the two were superimposed,

ignoring the time lag, the expected hysteresis loop, although small in magnitude, was seen. Maintenance of strict identity between the site of measurement of the two variables is difficult at best. If there has been a longitudinal displacement of the aorta, and hence of the circumference recorder, through influences other than the arrival of a volume pulse, a seeming "phase lag" between the two recorders could be produced.

Curiously enough, with isolated strips of arteries, the time lag is reported in the opposite direction for pressure leads. From this lag is calculated the viscous component of a dynamic modulus (48, 84).

Summarizing, we can say that despite many studies on the extensibility of the aorta and large vessels, it is still uncertain whether the presented stretch curves may be reflecting to such a great degree the techniques used that they are not readily illustrative of the characteristics of the wall. Work of the future will certainly be concentrated on measurements made on living vessels, that will include not only diameter change but changes in length, and perhaps in wall thickness. There are not sufficient data to allow a well-based speculation as to how the *in vivo* measurements might fit with those obtained from isolated specimens. The question of how muscle contraction might affect tissue extensibility, for the aorta and for the muscular arteries, is yet to be definitively answered. Whether an expression of extensibility in terms of a modulus is the most satisfactory tool remains questionable.

ACTION OF THE AORTA AS A CONDUIT

Pulsatile Flow in Rigid and Distensible Tubes

Since the aortic flow is never steady, we can turn immediately to a consideration of pulsatile accelerations and decelerations rather than deal further with the classic hydrodynamic equations. As a start, let us visualize a piston pump connected to a rigid pipe of uniform bore, with the piston being driven by a large force. Let us leave the distal end of the pipe open, so that a flow through can be established. Also, let us imagine a valve system so constructed that the barrel of the pump can be filled, during piston withdrawal, from an external reservoir. To start a pump cycle, the first tiny forward movement of the piston will produce a compression of the adjacent fluid. This initial compression will represent a high pressure—one that cannot be recorded, since any manometer used would

of necessity have a membrane, the resistance of which toward displacement would be less than that of the fluid or the rigid pipe walls. Once the involved force is sufficient to overcome the frictional resistance to fluid displacement, or to overcome the inertia of the fluid column, flow can start. While the time interval between may be short, we can say that there will always be a temporal separation between the creation of the pressure force and flow through the tube. This is commonly spoken of as a phase lag, with pressure leading. The definition of the physical forces and the quantitation of such lags, for both rigid and distensible systems, have occupied the attention of many physically minded workers of late (33, 48, 54, 60, 70, 85, 139). I do not consider myself qualified to judge the relative contributions of these papers.

Now let the piston complete its stroke, and reverse. The pressure in the pump will show a sharp fall, the amount depending upon the speed of inflow from the side reservoir. Since a pressure gradient has been previously constructed in the pipe to produce displacement toward the open end, or, if preferred, since fluid has already been accelerated toward this end, flow will continue for a brief interval despite the pressure fall in the pump. Once again, then, we have a phase lag, and the fluid column can be said to have an inertial force. If the pump strokes are repeated at a rapid frequency, the flow per cycle will be related to how well matched the duration of each phase of the pump cycle is to the phase lag, as set by the frictional and inertial characteristics of the tube. This principle of matching can be illustrated by another model. Suppose a U-tube mercury manometer is made to oscillate by a periodic blowing of air into a side arm on one side of the U-tube. The first buildup in air pressure will displace the mercury, and after this the mercury column will oscillate back and forth, the period being conditioned by the size of the tube and the other components of fluid resistance to flow. If the frequency of the air puffs matches that of the mercury column, the excursions will be reinforced. Conversely, if the generating frequency is out of phase with the mercury oscillations, movement of the mercury, or "flow," will be minimal.

Equations which relate flow to pressure usually express the phase lag in terms of a component of the frequency of the repeated strokes. This is simplest if the pressure buildup by the pump has a sinusoidal form. If the stroke is of a different form, the pressure curve is broken down into terms of a fundamental sine wave and a number of superimposed harmonics.

Matching with the resonant characteristics of the fluid-filled tube could be either with the fundamental wave or one of the prominent harmonics.

Use of the same pump coupled to a distensible tube of uniform bore and wall extensibility will present a somewhat different pattern. Because the wall can yield, a large part of the energy imparted by the piston can cause an increased tension in the tube wall. It is no longer necessary to construct a pressure sufficient to overcome the resistance of the whole fluid column, for as soon as the fluid resistance to displacement in the first small segment of tube is overcome, piston movement can displace volume into this segment. The pressure energy of this fluid will go into a stretching of the walls of the segment. If the wall extensibility is great (as with condom rubber), the first segment could accommodate all the fluid displaced from the pump, and there would be no appreciable pressure rise in the tube and no flow through its length. It might be pointed out that the molecular movements in this wall stretching are directed toward the side of the tube, so that the displacement pattern is more like that of turbulent flow in a rigid pipe than that of streamline flow.

If the tube is less distensible, only part of the fluid compression transmitted to the first segment will go to produce wall extension, for the fluid must retain enough pressure to prevent the elastic recoil of the stretched walls. This erects a pressure differential between the first and next segment of tube, a differential related to wall elasticity (which need not be identical with wall extensibility) and the fluid resistance of the second segment. When the differential becomes larger than the resistance, fluid displacement will follow. In a tube of uniform distensibility, then, except for the frictional energy dissipation, the same volume will be accepted, per unit length of time, by each successive tube segment as the first part or front of the wave moves through the tube. Hence, if the piston displacement is linear against time, the pressure in the pump and the upper part of the tube will simply remain constant, since all the pump outflow will be taken to establish the wave front as it moves from segment to segment through the tube. This pattern of a constant pressure can be demonstrated in a rubber-tube model. As the pressure front moves, flow through the stretched segments behind it will be streamlined. While the frictional cost of such movement will be small, the further the wave progresses the greater will be the cumulative energy dissipation. This analysis also means that once fluid displacement into the first tube segment occurs, the

first part of a pressure wave has been created. This wave will continue to move through the tube whether piston movement continues or not. Further piston movement does act to support the later parts of the wave, or to broaden it in time.

A sinusoidal piston movement leads to a rising and falling pressure in the upper end of the tube. This produces a pressure wave, positive or negative, which is propagated back and forth through the tube. No matter in which direction waves may be traveling through the tube, the pressure in any one tube segment at a given time simply reflects the balance between the amount of fluid entering it and that leaving it. The extensible tube should show a phase lag, too, but since only tiny segments of tube, acting more or less independently, presumably are involved, the resistance to fluid movement out of the pump should be very small. Hence a phase lag should also be small. It is well to note here that the loss in pressure in the aorta, due to frictional dissipation, is within the error of recording.

Our model of a tube with uniform distensibility has no counterpart in the arterial bed. Figure 5 shows four drawings taken from an earlier analysis of this problem (94), based primarily on the extensibility values given by isolated rings. That on the upper left depicts a part of the arterial bed of a dog, drawn to scale in respect to anatomical length and cross-sectional area at a pressure of 100 mm Hg. But in describing fluid displacements, we are more concerned with the propagation time of the pulse wave through a region than we are with actual length. The natural pulse wave moves slowly in the upper aorta, more rapidly in the lower aorta, and faster yet in the large arteries (10, 24). Suppose we redraw the figure so that the length now represents the distance traversed by the wave in a unit length of time (lower left). Next, since the pressure rise in the parts of the bed will be set by the segmental distensibility (neglecting wall hysteresis), let us redraw the figure (upper right) letting the assigned width represent the distensibility, expressed as $\Delta l/\Delta P$, rather than the cross-sectional area. Lastly, if frictional resistance is to be discounted as of small amount, we can neglect the effect of tube diameter per se, and group together into a single composite tube all vessels which might lie at the same time distance from the heart (lower right). Such a theoretical tube has a funnel shape, distensibility being great in the top (ascending aorta) and tapering down gradually to the stiff vessels that are farthest from the heart, those of the hind legs.

A linear piston displacement into such a tube will

FIG. 5. A reconstruction of the arterial reservoir of the dog. [From Remington (94).] For description, see text.

no longer produce a constant pressure in the upper end. The lower part of the tube will require less fluid to construct the same pressure rise. Hence the pressure in the pump will continue to rise as the wave front moves through the tube, the pressure rise being a function of the distensibility of the lower part of the funnel. This increased pressure at the upper end will also be propagated, so that we are now creating a whole pressure wave.

Quantitation of Fluid Displacement and Wall Distensibility Relationships

The propagation of the wave front is really the same as the initial displacement of fluid from segment to segment in the tube. The rate of this displacement should be a function of wall distensibility, and it should be possible to formulate the relationship in quantitative terms. This is another case where the textbooks have such a formula so well established that it has assumed the nature of a physiological law. The supporting evidence is far from adequate. Discounting all friction and other resistance factors, Korteweg presented a theoretical formula, and Moens (see 46), working independently, arrived at almost the same formula on the basis of experiments done with various distensible tubes. The latter used artificial waves which were relatively slow in their rate of pressure rise, and he used not the first part of the pressure wave for his measurements of wave velocity, but the time interval between successive peaks as the whole wave was propagated back and forth through his closed end system. His formula differs from that of Korteweg in that he had a constant of 0.9. We have shown (46) that the velocity of the peak of such

artificial wave is less than that of the start, by a factor not greatly different from Moens' constant. Using the Korteweg formula, then, the velocity of the wave foot (v) is related to an "elastic modulus" (E) of the tube, and the density of the contained fluid (ρ), thus:

$$v^2 = \frac{gEa}{2r\rho}$$

where g is the gravitational constant and a is the wall thickness. Neglecting hysteresis, E would be the same as S_d of equation 4 derived above. Hence by substitution:

$$v^2 = \frac{ga dT_d}{2r_d \rho dr} = \frac{ga dT}{2\rho dr} \quad (15)$$

If ρ is regarded as a constant, and given the value of 1.055 for blood, and a is taken as unity, then

$$v^2 = \frac{9.3 dT'}{2 dr} = \frac{4.65 dT'}{dr} \quad (16)$$

where T' is the tension per unit length of tube. Similarly, from equation 8:

$$v^2 = \frac{ga dPr_d^2}{2r_d \rho a dr} = \frac{4.65 dPr_d}{dr} \quad (17)$$

and from equation 12:

$$v^2 = \frac{ga 2dPV_d r_d}{2r_d \rho a dV} = \frac{9.3 dPV_d}{dV} \quad (18)$$

This equation 18 is the same as that derived by Bramwell & Hill (15) and has since borne their name. They further corrected the constant by multiplying it by the weight of mercury, so that pressure

would be in terms of mm Hg. Hence their formula reads:

$$v^2 = \frac{12.7 V dP}{dV}$$

Bramwell and Hill did not use the first slope to determine dP and dV , but appreciable increments in pressure and volume instead. Commonly the pressure increment is taken to be the pulse pressure, which strains the use of even ΔP . Because our methodology is not adequate to give dP and dV values, we have no right to use the above equations. If, instead, the formula is derived from equation 11:

$$v^2 = \frac{g \alpha \Delta P V_d (2r_d + 3\Delta r + \frac{\Delta r^2}{r_d})}{2r_d \rho \alpha \Delta V}$$

$$= \frac{12.7 \Delta P V_d (r_d + 1.5 \Delta r + 0.5 \frac{\Delta r^2}{r_d})}{r_d \Delta V} \quad (19)$$

Actually, $\Delta r^2/r_d$ is so small it can be practically neglected, so that

$$v^2 = \frac{12.7 \Delta P V_d (1 + 1.5 \frac{\Delta r}{r_d})}{\Delta V} \quad (20)$$

Validation of these formulas has centered on the Bramwell and Hill equation. The earlier results, which have been reviewed (46), offer no clear evidence that the velocity of artificially generated or natural pressure waves shows either a quantitative or qualitative agreement with values predicted by the formula, when it is applied to stretch data taken from isolated vessels. The solid line of figure 6 shows an average relation of pulse wave velocity to diastolic pressure for some 200 pulses of a living dog, taken from the aortic arch to the diaphragm. The broken line shows the velocity calculated, using equation 19, from the continuous second stretch curve given in figure 3. Agreement is certainly not good. If the mean slope for each loop given in figure 3 is used instead, then, as shown by the dotted lines, agreement with the actual becomes qualitatively better, with equation 20 giving a better fit than 19. But the mean slope can have little significance as far as the propagation velocities of the parts of a wave are concerned. The speed of the wave front should be dictated by the slope taken at the beginning of the stretch phase of the loop. Calculation from these initial slopes, using equation 19 (which is here valid), gives the

FIG. 6. Relation of pulse wave velocity to diastolic pressure. Solid line, actual values from a living dog. Broken line, calculated (eq. 19) from continuous stretch curves of fig. 3. Dotted line, closed circles, calculated (eq. 19) from mean slopes of loops shown in fig. 3. Dotted line, open circles, calculated (eq. 20) from mean slopes of loops of fig. 3. Crosses, calculated (eq. 19) from initial slopes of stretch phase of loops of fig. 3.

unconnected crosses of figure 6. These velocities are greater than the actual by 10 to 20 per cent.

In our earlier study (103), in which we compared a curve such as the broken line of figure 6 (based, however, upon a careful compilation of the stretch curves of all rings, taken in sequence, from the aorta being studied) with the actual, we believed that the underestimation would be correctable by using the slopes resulting from a hysteresis steepening of the first part of the stretch curve. The loops obtained in this earlier study were not numerous, and we did not attempt any quantitative verification of this belief. Further, and unfortunately, in this study we used both a rubber tube and the excised aorta, leaving the implication (although it very definitely was never stated) that the two behaved similarly. With rubber, the initial slope of the stretch phase of a loop proved clearly dependent on the rate of stretch. In keeping, the propagation velocity of artificial pulses through a rubber tube was found to be directly related to the rate of initial pressure rise. But with the aorta, using either artificial or natural pulses, there was no similar relation between the rate of pressure rise and the wave velocity. My more recent evidence (96) that a dependency of the aortic stretch curve upon the rate of stretch is minor is quite compatible with this finding.

A calculated velocity for the wave start, in excess of the actual velocity, may be explained by four

things. 1) The loops given by an isolated ring may be much wider than those found in the living aorta. Evidence was cited above that this might be true. 2) The velocity may be dictated not by the wall extensibility, but rather by the force of elastic recoil. Calculation from a stretch-release curve would indeed give smaller values. The question is what amount of stretch should be used to produce pertinent stretch-release curves. 3) The distensibility slope of the aorta during life may be entirely different from that indicated by the isolated rings. The data of Peterson (91), for example, seem to have it greatly different. 4) Factors which act to slow the pulse wave should be introduced into the formula. To the extent that the aorta acts as a rigid tube, fluid resistance toward flow can act in this manner, as will a phase lag between the pressure pulse and the corresponding fluid displacement. Many workers now accept the presence of an appreciable lag. As will be seen, acceptance of such a lag cannot be readily reconciled with the failure to find a correlation between wave velocity and the rate of pressure rise, as mentioned above.

Phase Lag and the Harmonics of the Arterial System

Since phase lag is formulated in terms of the frequency of harmonic components, the first step is to perform a Fourier analysis of the pressure wave. For this, a sinusoidal fundamental wave must be selected. Since such a fundamental is not readily apparent in the contour of the natural pulse wave, it is selected on the basis of a time duration (123, 124). Usually the length of the pulse cycle is used. As emphasized by McDonald in the introduction to his book (84), such a mathematical analysis can start from one of two premises. First, we can assume that each pulse is an isolated or transient phenomenon, with the aortic volume being almost static when a new cardiac ejection and sudden flow acceleration are begun. Second, we can say that the heart rate is virtually stable, so that the ventricle is repeatedly pulsing the arteries at a set frequency. The latter premise makes the cycle length a true measure of the wave fundamental, makes the harmonics relatively reproducible from beat to beat, and makes all the mathematical compilations very much easier. A change in heart rate will vary the contained harmonics and alter the phase lag between pressure and fluid displacement. It will, then, alter the wave velocity.

But the fact that an analysis on the basis of a uniform heart rate is easier to make does not mean that the premise is correct. Much evidence can be

quoted for the stand that each pulse is indeed an independent event. Strict regularity of the pulse rate is infrequent, usually being found only in rather prolonged experiments in animals under deep anesthesia. In the unanesthetized dog or human, variation from cycle to cycle is clear. In this variation the diastolic period is affected predominantly or exclusively. The pulse contour during systole, and its duration, is affected but little. Further, when the heart rate changes outside the limits of such beat-to-beat variations, systolic durations and contour are altered far less than is the cycle length (100). If the fundamental is reset each time this cycle length changes, a different harmonic picture will be required to construct the same systolic pressure contour. If the fundamental is taken as the average cycle length for a number of pulses, then we must proceed cautiously in interpreting the influence of the harmonic pattern on the contour of any single pulse of the group.

The whole approach seems more hazardous, too, when it is recalled that the length of systole almost never equals half the cycle length. This makes the heart quite unlike most pumps. Perhaps it would be more logical to use twice the length of the systolic period as the fundamental wave. This might be done for a central pulse, but certainly not for a peripheral one, where the incisura has been lost through damping.

Believing in the principle of a stable heart rate, McDonald (84) would have the velocity of the wave foot increasing with the heart rate. He offers no experimental support for the claim. We have looked often for evidence of such a dependency on heart rate and, with the single exception presented below, have not found it. However, McDonald has calculated that in a vessel the size of the aorta neither the viscous resistance factors nor the pulse frequency would affect the velocity to significant degree. In a smaller vessel, such as the femoral artery, he calculates that the viscosity would slow the velocity by about 10 per cent, and an increased heart rate might restore it to the value expected from the Bramwell and Hill formula. Much larger changes than these would be needed to correct the formula if the data given by the crosses in figure 6 are correct.

We did offer evidence (46) that a slower foot velocity was seen in the early part of the response of an animal to an injection of acetylcholine, when the heart rate was slow, than was seen later when, at the same diastolic pressure levels, the heart rate increased. A similar effect at higher pressures has

not been observed. We then attributed the velocity change not to the heart rate but to a changing hysteresis loop behavior of the wall. A long diastolic interval could allow more time for recovery after a stretch, and the diastolic size, and hence the distensibility modulus, would be thereby reduced. It is less clear now (96) that the difference in this size could be sufficient to account for the difference in wave velocity. Yet it remains possible that the correlation with heart rate was still only coincidental, and that when the pressure was abruptly lowered the slope of the stretch curve could be shallower for the first few beats than it would be after the pressure had remained low for some time.

Most especially, if we regard the pulse wave as an independent phenomenon, the velocity of the wave start would be affected least by a change in harmonic frequency. The upper parts of the pressure pulse could have their propagation speed affected to greater degree by these frequencies or by the speed of the pressure upstroke. A different velocity for the parts of the wave was fully accepted by Bramwell and Hill simply on the basis of their formula. They went further (14) and held that the difference in velocity could be such that the anacrotic rise of the pulse would progressively steepen in transit until finally the wave force would become unstable, and a "breaker" (like that seen when an ocean wave enters shallow water) would form. Evidence of such breaker phenomena was seen when pulses were generated in a bicycle tire. As will be described later, evidence is not clear that the natural pulse does so progressively steepen during propagation, and there is no evidence at all for sudden pressure vibrations that would mark a breaker. However, the calculated differences in velocity between the start and the peak of a natural wave are not large enough to create a breaker within the length of the aorta.

If there is a velocity differential between the parts of the wave (and it would appear to be quite small if present),² it could reflect the progressive increase

² There is an obvious discrepancy between the statement that there is no clear evidence for a difference in propagation velocity of the parts of a natural wave and our published results (103) which showed clear differences in transit time for the parts of an artificial wave. There are few inflections on the natural pulse form which can be measured with the necessary precision to establish a difference in propagation velocity. The start of the wave and the incisural notch can be so timed, and these two parts of the pulse contour appear to move with the same velocity. Since we have no clear idea as to which tension-length slope should be used to predict the velocity of the incisura, or to which volume on the stretch-release curve this slope should be referred, this identity of velocity with that of

in the stiffness modulus as the reference volume increases, without requiring a dependency upon the harmonic frequencies. Landowne (72, 73) did show that when small impact waves were formed at a point on the human brachial artery, the speed of their propagation was faster if they fell during the systolic portion of the pressure pulse than during the diastolic portion. The propagation velocity of these small waves was much greater than that of the natural wave. Van Citters (125) believes that the velocity is of the order to be expected if they were being transmitted by longitudinal strain through the wall itself, rather than by fluid accelerations within the artery.

Landowne (71) has also shown that, with a rubber tube or umbilical artery, either small impact waves or rapidly repeated sinusoidal waves moved at a velocity which bore a direct relation to the frequency. Our experiments showing a dependency of wave velocity upon the rate of stretch of rubber fit with this (46). The umbilical artery has a uniquely large time-dependent factor in its visco-elastic behavior (141), so that it would not be at all unreasonable that the velocity could also show a clear rate dependency. These results should not be regarded as transferable to the aorta, and perhaps not even to arteries such as the femoral or carotid. We are left, then, with the conclusion that the actual pulse wave velocity remains to be explained in a quantitative way. A mathematical analysis of the determinants of pulse wave velocity is presented in the chapter by Hardung (49).

We still have the fundamental question as to whether there would be an appreciable time lag between the pressure pulse and the fluid displacement, or the movement of the pulse wave from segment to segment through the tube. The idea of a large lag was presented first in the papers of Peterson (89, 90). He perfected a mechanism which could produce a very rapid input of fluid into the ascending aorta, and thereby generate pressure curves, of rather strange form, which were propagated. The shape of these curves was explained on the basis of a summation of three forces. First, a very small amount of fluid would be driven into the aorta more rapidly than the walls could stretch, so that, just as in a rigid pipe, there would be a sudden rise in pressure.

the wave foot may be coincidental, and not be evidence for or against a dependency of wave velocity upon frequency. It should also be stressed that while the wave parts of the artificial wave moving through an excised aorta showed different transit times, these times were not conditioned by the rate of pressure rise or fall.

This initial peak he labeled the acceleration transient, and its force was equated to the small fluid mass involved times the acceleration. Next, he added a force which increased with the velocity, representing the resistance offered to fluid displacement through the tube. This reached significant proportions only as the volume displacement did, which placed its contribution later in time than the acceleration transient. Finally, after a time lag, he added a straight line increase in pressure to represent the force necessary to prevent an elastic recoil of the walls as they were stretched.

Certainly the presence of these three forces in constructing an aortic pulse cannot be denied. The problem is to ascertain how large a role each of them plays, and how much of a time delay between them exists. Peterson's acceleration transient lasts for many milliseconds. While wall hysteresis could, to use a term employed long ago (46), make the vessel segment show a "reluctance to stretch," no studies on isolated rings indicate that the reluctance could last nearly this long. Just as crucial is his claim that the same pressure excess which marks the acceleration transient would persist through the whole systolic period, so that all the pressure pulse would have a higher value than would be predicted from a pressure-volume diagram taken from stretch data. The fact that he dealt with the whole arterial bed as a lumped system has made it difficult to follow his argument.

Rather than a discrete time lag of this sort, other workers are supporting the presence of a sinusoidal phase lag (34, 36, 83, 120, 128, 129). Using an electrical analogue, the aorta is said to have an inductive, capacitive, and a resistive impedance to flow. Of these, the inductive and resistive factors would be in phase, but the capacitive would lag up to 90 degrees. In hydraulic terms, the first of these is called inertance, which represents the mass of blood displaced into the tube segment times its acceleration. Opposing this inertance is the compliance (capacitance) reflecting the volume taken to accommodate the wall stretch, and the resistance, which represents all fluid and wall factors that cause dissipation of energy as heat. In an actual vessel subjected to pulsatile flow, the interrelation of the three would be dependent upon the rate of change in the driving pressure, usually expressed in terms of the frequencies of the harmonics. The better matched these frequencies are to the inherent frequency of the vessel compliance, which is a function of the visco-elastic properties of the wall, the greater is the flow into and through a

segment. The most proper match would be at the "resonant" frequency of the vessel.

If an isolated vessel is suddenly stretched and then allowed to vibrate, it will show a definite period of oscillation (77). This frequency will be different at various pressure levels and with different parts of the arterial system. It also can be changed by any factor which influences the visco-elastic properties. The matching frequency between a segment and the driving pressure is therefore subject to considerable variation.

But it remains uncertain why such factors should play a significant role in a distensible tube composed of tiny segments. Certainly any final analysis of the pressure-flow relation must reconcile the recent data, based on the dictum that a phase lag must be present, with the older descriptive work, which includes evidence of a general absence of effect of any physiological factor other than the diastolic pressure level on pulse wave velocity, the details of pulse contour change which takes place during propagation (to be treated later), and the actual time relation between flow and pressure curves. The last of these has been least well covered. Records of the flow pattern seen at different parts of the aorta have been presented, and such records have, superficially at least, much in common. But discrepancies exist between them in regard to quantitation, timing of peaks, and amount of end-systolic backflow. (27, 53, 56, 84, 120). Unfortunately, a simultaneously recorded pressure pulse is so rarely given that one can never be sure whether the cardiodynamic conditions were enough alike in the different experiments that one should expect similar flow curves.

In the ascending aorta, the flow rises sharply to a peak reached in early systole and then falls more gradually to reach a zero value, or below, at the time of the aortic valve closure (fig. 7). The flow then remains negligible throughout the diastolic period (119), or may show a small sinusoidal increase in diastole (131). In records taken from other parts of the aorta, the amount of retrograde flow seen just after the end of systole progressively increases as one moves out the vessel, and the diastolic wave also increases in magnitude (119).

It may be well to digress into a semantic problem that continually proves worrisome to students. The point is frequently made or implied that there is a clear distinction between the fluid displacement that accompanies the movement of a pulse wave and the "stream flow" through the vessel. In the aorta there really is no stream flow as such, and fluid displace-

FIG. 7. Carotid pressure pulse (A) and ascending aorta flow (C). [From E. Wetterer (131).] B = change in volume uptake curves for arterial bed regions. Broken line of C = the summed uptake values taken from B. D = change in volume uptake as calculated from a hysteresis loop, as taken from fig. 3. The summed uptake values are given in C as the dotted line.

ment simply accompanies the movement of the pulse. This displacement is toward the periphery in systole, but some may be toward the heart for a period in diastole. It should not be difficult to understand that the molecules involved in such displacements in the lower aorta, for example, are not the same ones as left the ventricle during the corresponding ejection. The stroke volume is of the order of a fourth of the aortic volume. In contrast, a stream flow is established in the stiffer resistance vessels, which approach more nearly the characteristics of a rigid tube. Another way of saying this is that flow through the aorta starts and stops, rather than being continuous.

At present, the aortic flow curves available offer no clear indication of the amount of time lag between pressure and fluid displacement. Spencer (119) makes the statement that in the upper aorta pressure and flow start together, but he offers no supporting figure. If this is true, any phase lag will be based simply on a relatively slower increase of flow than of pressure. On the other hand, the left ventricle usually develops a pressure above the aortic level before ejection apparently begins, which excess is then gradually lost (98). Thus there appears to be a true time lag of about 5 msec, similar to that en-

visioned by Peterson. But a study of pressure pulses taken from adjacent parts of the aorta offers no clear evidence that a similar excess and time lag exist there. Thus, after the initial delay between ventricle and ascending aorta, the pressure pulse seems to be propagated at a steady rate through the aorta (98, 99).

At present, a major obstacle in the interpretation of the presented flow curves is a lack of a reference standard against which they can be compared. Quantitatively, the curve from the ascending aorta should integrate to the stroke volume less the coronary flow. But our knowledge of the time contour of cardiac ejection rests only on cardiometer curves, which come from open-chest animals and bear distortions that make one question the value of a too detailed study of their time-flow dimensions. Flows taken from other aortic regions can be related to the stroke volume only if one assumes a distribution of volume between the parts of the arterial bed.

Construction of a Hypothetical Ejection Curve

It might be of interest to construct a hypothetical ejection curve, derived from the contour of the central pressure pulse (104). This requires that all animals be assigned the same wave transmission time and the same arterial distensibility, the latter taken from an average of stretch curves of isolated rings. Certainly no claim can be made for the accuracy of such curves. All we do know is that the total stroke volume derived in this way usually agrees reasonably well with that given by a direct measurement (94). In this construction the arterial funnel, as shown in figure 5, is divided into segments, the lengths of which are approximately 10 msec of transmission time. The total volume uptake of the arterial region is then divided by the number of segments included, with the various segmental uptake curves starting in sequence every 10 msec. This derivation assumes that: *a*) the aortic pressure pulse, as taken from the ascending aorta, has no distortion because of a contained acceleration transient; *b*) the wall stretch shows no hysteresis lag; *c*) the control pulse is propagated as an entity, without damping and without augmentation; and *d*) there is no time lag between pressure change and the corresponding fluid displacement.

Suppose we take first the pressure pulse presented by Wetterer (131) corresponding to his ascending aorta flow pulse shown in figure 7. This pulse is obviously from an open-chest animal, the length of systole probably indicates that the animal was cold,

and the contour is not one we would regard as representative of that to be obtained from an animal in good circulatory condition. The ascending aorta and arch are taken as the first tube segment. From our tabulated pressure-volume tables (104) a volume uptake curve can be constructed for this segment in 10-msec intervals, starting at the time the central pressure pulse begins its upstroke. Because, in the Wetterer experiment, the ascending aorta had a flowmeter attached, we have arbitrarily reduced the volume uptake of this segment by one half. Rather than plotting the total uptake, only the net gain or loss of volume for each time interval is given as the solid line curve of figure 7*B*. While the pressure in this segment is still rising, the volume will be increasing. When the pressure falls in late systole, there will be a net loss of volume.

The thoracic aorta and head and foreleg arteries are grouped together in the next part of the funnel, and it takes the wave some 30 msec to move through the whole. Hence, for uptake calculation the total region is divided into three parts, displaced 10 msec behind each other. The summed net volume change for all three is given by the broken line, labeled *H*, in figure 7*B*. Next, the pressure wave invades the abdominal aorta and visceral arteries, which takes another 30 msec. The summed volume change of the three units involved is given as the dotted line (*I'*). Finally, the summed changes of the three leg vessel units are given in curve *L*. Flow through the ascending aorta must not only accommodate the volume acceptance of more distal arteries, but must supply systolic drainage through the arterioles as well. The calculation of this latter will not be gone into here (see ref. 44), but it is indicated in figure 7*B* by curve *D*. Ascending aorta flow now should equal the algebraic sum of all these curves at any given time instant. The value obtained is per square meter of body surface. It is assumed that the dog Wetterer used was medium size, i.e., had about 0.6 m² surface area. The use of this assumed value means that we should not expect quantitative agreement between the derived curve and the actual one, but only qualitative agreement. The total flow calculated in the above manner is given as the broken line in figure 7*C*. The actual curve presented by Wetterer is given by the solid line. The calculated values therefore indicate a flow increasing more steeply in early systole, and decreasing sooner and more sharply after the peak. This discrepancy in flow might have four causes: 1) the flowmeter might be slurring the actual

curve; 2) there might be a distortion of the aortic-flow curve because of vessel constriction produced by the meter; 3) there might be a true time lag, of appreciable proportions, between the pressure curve and the flow curve; and 4) wall hysteresis might change the form of this calculated flow curve. The influence of the last of these can be directly tested. If the volume uptake values are calculated from a hysteresis loop of the same pattern as those given in figure 3, the rate of volume gain in early systole would be decreased, and there would be little volume change while the pressure first starts its fall in late systole. The summed flow curve, as given in figure 7*C* by the dotted line, differs but little in form from that given by the broken line. Hence it would be difficult to reconcile the calculated curve with the actual with even a large amount of vessel hysteresis.

A similar calculation was done for the only three pulses presented by Spencer and co-workers (119, 120) which have accompanying pressure pulses. The flow recorder here was on the upper thoracic aorta, so that the uptake of the arch, head, and foreleg vessels were omitted when the volume changes were summed to give the flow curve. The same type of discrepancy between the calculated and the recorded flow pattern is again seen (fig. 8). It might be noted that these pressure pulses are unusual in that they have a very steep initial rise in pressure, with a relatively flat systolic crest. This might be evidence of an effective aortic constriction by the meter. If so, the flow profile in the lower aorta would not be expected to match the form of this pressure pulse.

On the premise that flow should lag behind the instantaneous pressure, Fry and co-workers (34) derived an equation in which the pressure difference between two points in the aorta was equated to the sum of an inertial term and a frictional resistance. Solution of their equation was achieved by use of an electronic computer. After checking their equation by use of a sinusoidal pump with a tube (rigid?), they proceeded to construct a flow velocity curve for the upper aorta, using catheter tips 6 cm apart for the pressure recordings. Not knowing the exact positions of the catheters, one is uncertain as to just what vessel segments should be included in an attempt to construct a similar flow curve on the basis of vessel distensibility. We used the whole aorta, as though we were calculating a cardiac ejection curve. Not knowing dog size or diastolic aortic dimensions, the calculated peak flow value was

FIG. 8. Pressure and flow values given by Spencer. Pulse *a* from Spencer & Denison (120); pulses *b* and *c* from Spencer *et al.* (119). Dotted line, summed arterial bed uptake values, as described in text.

arbitrarily made to coincide with the presented values. The agreement in contour between the curve presented by Fry (solid line, fig. 9) and that calculated (broken line) bears a good deal of resemblance to those seen with the actual flow curves. It should be mentioned that the differential pressure recording presented by Fry indicates a peculiarly long delay period between the two recording catheters, with a slow transmission velocity through that particular aorta (about 3 M/sec).

These constructions provide presumptive evidence, then, that there is a delay between the pressure and fluid displacement curves. There will certainly continue to be interest in the factors which contribute to this lag. Whether harmonic analysis of the pressure pulse curves may be the most profitable tool for this assessment remains to be decided. It is important that we do not let sophisticated mathematics allow us to lose sight of the basic processes by which a distensible tube seems to be filled. Volume is displaced from segment to segment, establishing and maintaining a moving pressure wave. Since the distal parts of the aorta are stiffer than the proximal, we would not expect that the pattern of fluid displacement out of the arch would be qualitatively similar to that of the pressure curve, for the amount of fluid leaving the upper aorta would be decreasing when the pressure was rising. Toward the end of systole, when the wave front has invaded the whole network of distensible

vessels, flow would fall sharply to a low level which represents mainly the drainage loss from the bed. At this time, the aorta would be behaving more like a rigid tube.

Judging from cardiometer curves, ventricular ejection starts slowly, then rapidly attains a maximal and constant rate which lasts through the first part of systole. The outflow then slows, reaching a small value some time before the valves actually close. Because the first outflow, although slow, is confined to the ascending aorta, the pressure rise produced must be relatively large. As the wave moves through the aorta, an even faster ejection rate will produce less rise in ascending aorta pressure. This tendency is in part offset by the stiffer walls of the more distal vessels. But in any aortic segment a pressure rise simply means that more blood is entering than is leaving for the more distal regions.

A pressure difference curve based upon a subtraction of pulses taken at two different sites can be misleading. Even assuming no change in contour, until the wave reaches the distal recorder the difference will be but a replica of the proximal pulse. When the pressure upstroke in the peripheral recording begins, this difference curve must show a sharp inflection and a fall, depending upon the duration of the first steep pressure rise and the separation of the recorders. As long as pressure is still rising in the proximal segment, the difference should remain slightly positive.

FIG. 9. Pressure and flow values given by Fry *et al.* (34). Broken line of B, calculated flow values as described in text.

When it starts to fall, the difference should swing to a negative value. This does not mean that flow down the aorta will then cease. The volume displacement is part of a wave movement, and the pressure differential simply reflects the time lag between the wave's arrival at two points in the tube. Such a continuation of fluid displacement toward the periphery, despite a negative pressure differential, could properly be called an inertial property of the fluid. What all workers are seeking is a complete description of what we mean by a wave, and what factors contribute toward its progression through the tube.

Before leaving the descriptive model, it should be pointed out that no length dimensions were placed on the tube segments that were acting independently. With wall fibers distributed longitudinally as well as circularly, there cannot be such an independence of action of tube segments. A unit of a distensible tube must have a finite length, which, however, has not been defined. This tying of segments to each other must give a distensible tube some of the characteristics of a rigid tube. However, it remains rather inconceivable that a whole aorta could act as a single bound entity, and could be given a single lumped resistance value.

To summarize this section on the behavior of the aorta as a conduit, the initiation of flow through a

rigid system certainly requires the acceleration of a whole column of fluid, an overcoming of fluid resistance for the whole length of the tube, and a phase lag between pressure built up at the generating source (pump) and the flow out the end of the tube. In such a rigid system, resistance factors can certainly be treated as a unit. With a distensible tube, however, depending upon the stiffness of the wall, only a small segment of fluid need be accelerated in any given unit of time, and the fluid resistance and the phase lag can be relatively small. A model has been presented in which a pressure wave is propagated from a minute segment of such a tube to the next adjacent segment. Of course, the tube is linked longitudinally by extensible fibers, and the length of what is being called a tube segment cannot be defined. But it is not clear that the current trend of treating pressure-flow relations in the aorta as though resistance was lumped and as though there were an appreciable phase lag between pressure and flow is helping our understanding. The propagation velocity of the wave must be linked in some way to tube dimensions and to wall distensibility, but no completely satisfactory formula for quantitating this relation appears yet to have been presented.

THE AORTA AS A BLOOD RESERVOIR

Changes in Central Pulse Contour During Propagation

In the description of how fluid displacement through the arterial bed might be calculated from the distensibility values of the various vessels, and the course of pressure change in the ascending aorta, the assumption was made that the central pulse would be propagated intact. This assumption is clearly false. The pulse contour is modified during transmission, this modification resulting perhaps from damping, or from a poor matching between the frequencies of the volume input curve and those set by the distensibilities and flow resistances of each arterial segment, or from an augmentation of "matched" frequencies, or even from superposition of a wave reflected from the periphery upon the incident wave. It should not be implied that, because pulse contours change, the whole method of calculation of the form of the cardiac ejection curve is invalid. If the contour changes do not appreciably alter the total displacement of fluid out of the ascending aorta, the total quantitation need not be greatly in error.

Contour differences between a central and a

FIG. 10. Reconstruction of aortic-pressure pulses, showing comparison between control in aortic arch (dotted lines) and records taken simultaneously with their controls at indicated distances down the aorta from the arch (solid lines). Below, five of the above ten, semi-diagrammatically superimposed on a somewhat larger scale, with a representative control. [From Hamilton & Dow (42).]

peripheral pulse were recognized even in the days when pressure recordings were made using low frequency manometers. When Frank (28) developed his high fidelity manometer, he established this difference in precise terms. This was verified and amplified by the work of Wiggers and his associates (1, 135, 136) and Hamilton and his group (40, 42, 140) in this country, as well as by continued work in Europe (17, 29, 57, 58, 75, 115, 117, 133). In contrast to the broad systolic crest of the central pulse, the femoral artery pulse, for example, shows a high, narrow systolic profile. Sudden slope changes, such as the shoulder of the central pulse and the incisural notch, are no longer present in the distal vessel, having been lost through damping (fig. 10). Such damping is most obvious when the aortic pressure is low, and least obvious when the pressure is at hypertensive levels. This is probably related to the fact that the visco-elastic properties of the wall are more prominent at low pressure levels.

The changes in contour are similar to those that would be obtained if a central pressure pulse were recorded by a slow-frequency manometer system, which would allow an overswing of pressure in systole, and an exaggerated fall to a low level in early

diastole. The German workers, after Frank, have therefore thought of the portion of the arterial bed which stores blood in systole, i.e., the arterial reservoir or Windkessel, as having a lumped distensibility value, like a manometer (12, 17, 58, 132). It should be remembered, of course, that the distensibility of the arterial bed is not that of a single membrane, and it does not follow that the arterial reservoir could vibrate as a single unit as a manometer system does.

Despite much descriptive work on the contour changes which attend propagation of the pulse, our basic knowledge of the underlying principles remains incomplete. In their classic paper on this subject, Hamilton & Dow (42) presented for the first time a mapping of the changes in pulse form in the dog as recorded serially from various points in the aorta (fig. 10). This mapping reveals that as the wave moves toward the periphery the steep initial anacrotic rise remains unchanged in slope, but persists for a longer time. Hence the deflection marking its end, or the shoulder, comes at progressively higher pressure levels. The systolic peak becomes gradually narrower, so that the time from the start of the pulse to the peak is reduced. Hence, in spite of the transmission delay of the start of the wave, the peak is reached at

just about the same time in all pulses taken from the lower part of the aorta. It is most difficult to time the peak of a pulse exactly, but this approximate identity was taken as evidence that this peak was "standing." This suggests that the aorta was achieving a "resonance" with the first transit of the pulse wave.

Resonance and Standing Waves

To explain the resonance concept, let us visualize a somewhat elongated rubber balloon, filled with fluid, and connected at one end to a syringe. A sudden input of fluid would start the bag oscillating, due to a sloshing of fluid from one end to the other with a reversal of movement, or a reflection, taking place at each blind end. The period of such oscillations must reflect the time required for the fluid slosh to traverse the balloon, and therefore is related to the conduction velocity of the fluid wave and the length of the bag. The first of these is a function of the distensibility of the part of the bag through which the wave is moving, as described earlier. If the wave length of the slosh is just twice that of the transmission time through the bag (or a simple multiple of it), we could say that the bag was resonating, for *a*) the pressure changes at the ends would be just 180 degrees out of phase; *b*) the peak pressure, produced by a summing of the incident wave with the reflected wave, would be reached at the same time through half the length of the tube. This means that there would be a point of minimal pressure oscillation, or a "node," at the mid point of the tube, and all peaks and pressure troughs seen on either side of this node would be "standing" through half the tube; *c*) the time interval between two successive pressure peaks, as recorded from any point in the tube, should be a constant, and be an index to the length of tube and the wave velocity.

The records of Hamilton and Dow suggest that all three criteria can be met in the arterial system. There are pressure oscillations at the two ends of the dog aorta which seem 180 degrees out of phase, and which maintain approximately (but not exactly) the same period until they are damped out. The amount of pressure change with such oscillations is much smaller in the arch of the aorta than in the abdominal aorta, just as the distensibility of the two regions is different. There are times when all three criteria are not met in the dog, but more recent mappings indicate that what seems to be a true resonance very often is achieved (4, 101).

The carotid artery (or whole head system?) shows

no similar oscillations, or even any great change in pulse pressure with outward propagation of the pulse (39). In man, the arm system shows augmentation of the pulse pressure but not resonance as defined above (108). Records made in this laboratory indicate that the foreleg system of the dog produces pulse contour changes similar to those seen in the human arm. Further, the aorta-femoral system does not show such resonance or even clear oscillations in very small animals (140). There is question whether resonance occurs in an animal as large as man (108). The German workers do believe the human aorta to show resonance, but, as will be discussed later, their conclusion is not based on a standing peak for the peripheral pulses.

Attempts to design a model that could illustrate the prompt achievement of resonance, as occurs in the dog, have not been successful. Certainly, experiments in which independent pulses were generated in a closed and moderately long rubber tube (46) provided little insight into how it would be possible to make a previously quiet bag resonate with the first propagation of a pressure pulse through it. Granted that if the time of volume injection was made identical to the transmission time of the wave peak through the tube, reciprocal oscillations at the ends would be seen from the time of completion of the injection. But if the injection period was appreciably longer or shorter than this, there was no such immediate resonance. Instead the formed wave peak could be followed back and forth through the tube, as it was propagated at a steady rate, and reflected at each blind end. Because the wave length changed during these propagations, the foot moving more rapidly than the peak, which in turn moved faster than the "tail," after several trips through the tube the wave could finally achieve a length equal to that which would make the tube resonate. Whether a given wave ever attained such resonance would depend upon the number of trips required to change its wave length, and the number that were possible because of incomplete reflection and continued damping. The change in wave length attending propagation was attributed to the hysteresis behavior of the wall.

Similar changes in the length of an artificial pulse were seen in a tied off but in situ dog aorta (46). This change is directly opposite to that predicted by the Bramwell and Hill formula, which would have the peak moving faster than the foot. Of course, artificial waves never attained the same rate of

pressure rise seen with a natural pulse, and they were truly independent phenomena.

McDonald (84) believes that because the natural pulse is but one of a continuous train of waves with virtually identical wave lengths, each ejection could serve to reinforce the component frequency which happens to match the transmission time through the resonating part of the reservoir. This premise would permit development of resonance with the first transit of each wave. But, by extension, this premise would also require that the pulse pressure augmentation be a function of the heart rate. Again, all we can say is that neither the pressure augmentation nor the period of the diastolic oscillations has been shown to have any relation to heart rate per se when the diastolic pressure remains the same. The reciprocal oscillations between aortic arch and abdominal aorta pulses in the dog appear to be the rule and not the exception. They appear with the first beat after a prolonged cardiac arrest, as with vagal stimulation; they are not clearly accentuated at any given heart rate; it is most difficult to so alter the cardiovascular status through nerve stimulations or injected drugs as to make them disappear.

The prompt achievement of resonance by the aorta would seem to require, then, that the whole vessel could act as a unit, and "mold" any ejection wave into a pattern consistent with its own resonant properties. Alexander (7) has used the analogy of an orchestral chime, which, when struck, vibrates at a frequency set by its own geometry, unaffected by the characteristics of the impacting force. Use of this analogy is not easily reconciled with the theorem that wave propagation is from tiny tube segment to adjacent segment. Instead the pressure rise in the upper end of the aorta would have to be able, by some mechanism, to throw the whole aorta into vibrations. Yet there is no evidence that this pressure rise "signals ahead" of the propagated pulse wave. There is no pressure change in the lower aorta at the time the central pulse is first being ejected.

One question which must be decided is whether it is the propagated pressure wave itself which sets the aorta into resonance. No alternative suggestion has yet been advanced, unless one can read into a paper describing the genesis of the ballistocardiographic waves the notion that whole body thrusts might induce this resonance pattern within the vessels (43). The propagated wave in an aorta has much in common with an artificial wave being propagated through a stoppered rubber tube, although the latter does not readily create immediate resonance. The

aorta should be even less conducive to the attainment of resonance than the rubber tube. There certainly is no single reflection point, for exit vessels are distributed along the whole length of the system. One would expect, then, innumerable returning waves bearing no necessary time relation to each other. Further, the exit vessels are not blind end tubes, but continue on to become the resistance vessels of the arterial tree. This has led some to the conclusion that the aortic reservoir should be considered as more comparable to an open-end tube, the resonant wave of which would then be twice as long as that of a closed-end tube (60, 134). On the other hand, Hamilton (38) has maintained that the sudden increase in the resistance to flow in these vessels will serve to produce the positive reflection. While such reflections could take place wherever the flow pattern is changed, as at a vessel bifurcation, or even in the curvature of the aortic arch, these reflections within the tube would be small when compared to those arising from the small resistance vessels. He has documented this belief by experiments done on a rubber tube model fitted with many small rigid tubes of high-flow resistance, but with a greater aggregate cross-sectional area, placed in series with the rubber tube (41).

Alexander (1, 4, 8) recorded pulses from the arch, the abdominal aorta, and the femoral artery of dogs under a variety of physiological conditions. Usually the two peripheral pulses showed simultaneous peaks, although at times they did not. If the central pulse was subtracted from the peripheral one, to give the contour of the reflected wave, two different waves in the subtraction curve could be seen. The first of these was taken to represent the propagated peak of the incident wave, "distorted" by damping and the other factors which may give rise to contour change during propagation. The second, a swell of more sinusoidal form, was the first of the resonant oscillations. When the two waves coincided, the femoral pulse pressure was at its greatest. In some central pulses, a late systolic trough could be seen that appeared simultaneously with the distal resonant swell. When the length of the ventricular ejection period was slowed through induced hypothermia (7), this trough came far enough ahead of the incisura to be clearly recognizable.

The resonant swell obtained by such a subtraction did not have the same wave length as the central pressure pulse. In fact, there is no real evidence that the whole of the incident pulse is reflected. When subtraction curves of the same type were obtained for human subclavian pulses (108), a reflected wave

seemed to be present, but it was small in magnitude and short in duration. It was as though only the first sudden acceleration of flow produced a reflected wave. Whether this should be regarded as a common finding, true for the whole arterial tree and also for a closed-end rubber tube, is not clear.

Hamilton & Dow (42) showed that when the aorta was occluded, the frequency of the pressure oscillations seen on a pulse was more rapid than that usually found in a normal dog. By moving the point of occlusion distally, they concluded that the "end" of the resonating system must lie outside the aorta. Taking the time from the start of the central pulse to the peak of a lower abdominal aortic pulse as equal to half the total resonant wave length, they calculated that the end should be near the knee, and the node should be in the lower thoracic aorta. Wezler & Böger (134) placed the end, which they took as the point of negative reflection, in the femoral artery near the inguinal ligament in the human. Schmitt (115) located the node in the abdominal aorta in man, and the end in the distal part of the tibial artery. This was based simply on transmission times of the wave, for the time delay from the heart to the node should also equal the time from the node to the end, and equal a fourth of the total interval between successive pressure peaks of a peripheral pulse. Similar studies by Wetterer and co-workers (58, 132) placed the end of the system beyond the ankle in the foot. An occlusion by cuff inflation of the legs shortened the interval between the systolic and the postincisural pressure peaks, which they reasoned could be true only if the cuffs were still proximal to the end of the system (59). There are two aspects of studies such as these that give room for concern. First, the pressure peaks of pulses taken from the leg arteries are not coincident with those of the femoral artery (fig. 11), nor are they timed to reciprocal oscillations of the central pulse. Of the

three criteria listed above for resonance, they satisfy only one, i.e., the time interval between peaks remains about the same as that seen more proximally. It remains possible that the truly resonant pulse form could be propagated with but little distortion of time relations through the leg arteries. This seems to be what happens in the arm vessels (108). Second, occlusion of the aorta seems to make it behave as a blind-end rubber tube would, and the waves which are propagated back and forth in this occluded length of vessel do not have the same characteristics as the natural wave. It may be that leg occlusion could introduce a reflection of the wave, and change the timing between peaks, but that use of the occlusion technique to identify the end of the resonant system is not theoretically sound. It should be repeated that our studies on aortic pulses in man (108) gave no evidence of a standing peak.

Alexander (3) believed that the node for the dog was in the upper abdominal aorta where the large visceral arteries exit. This is a point of sudden increase in total cross-sectional area, where the flow rate, relative to the vessel size, accounts for a large fraction of the total cardiac output. When he occluded the visceral arteries, the frequency of the resonant waves seen in femoral pulses was increased, and the preincisural trough of the pulse of the ascending aorta became less conspicuous. Unfortunately, the pressure was also raised by this maneuver, so that the changes evoked are not indisputable evidence for his hypothesis. Conversely, an intra-arterial injection of histamine into the visceral arteries decreased the frequency of oscillations (and also lowered the systemic pressure). Ryan and co-workers (114) repeated the occlusion experiments, and concluded that the pressure rise might have been sufficient to explain the changed frequency of the resonant waves in the femoral pulse, but observed that the occlusion did eliminate the preincisural trough of the central pulse. In general, however, occlusion of exit arteries has very little influence on the timing of the pressure oscillations (57).

Alexander (4) postulated that the aorta-femoral system was essentially two open-end systems in series, the region of visceral artery exit marking an open end common to both. Arrival of the incident wave at this area would be followed by a reflection of a negative wave back toward the arch to produce the preincisural trough. The incident wave would also be propagated into the lower aorta as a positive wave. Hence the two systems would be effectively resonating with each other.

FIG. 11. Pulse contours from peripheral arteries. [Redrawn from Kapal *et al.* (59).]

FIG. 12. A mapping of the change in pulse form in the dog aorta. Pulses from ascending aorta (R), descending arch (4), upper thoracic aorta (7), mid thoracic aorta (10), lower thoracic aorta (14), abdominal aorta (18) and iliac artery (22). [From Remington (100).]

The German workers have also been concerned about the effect the large visceral arteries might have on the resonant wave. They (58), like Hamilton, would locate the only significant reflection point in the small arteries. The influence of any single aortic branch as an independent reflection unit (particularly that of a vessel so far proximal to the "end" of the system as a visceral artery) causes them no great concern. Assuming the resonant frequency to be already established (they have presented no analysis as to how this might be achieved), they conclude that reflections in this branch would serve to augment the pressure excursion without altering the fundamental wave length of the incident wave. An example of this is seen when two manometers of different frequency response record in parallel a rapid pressure change; the records from both will be the same and reflect the response characteristics of the slower manometer. This would not explain Alexander's preincisural trough seen on the central pulse.

In a number of mappings of the dog aorta (99) I found that while in some pulses the late systolic trough could be seen, it was not present in pulses taken from the descending arch of thoracic aorta (fig. 12). Hence this trough apparently is not propagated back from the upper abdominal aorta, but rather appears *de novo* in the ascending aorta pulse. Although there were some time discrepancies between the systolic peaks of the peripheral aortic waves, there was a general tendency for a standing wave to occur. But this standing wave seemed to develop as a sinusoidal swell taking off from the broad crest of the propagated wave, and appeared first in the aortic arch or at least high in the thoracic aorta. Its size progressively increased as the wave moved toward the periphery. If this swell represented the first of a resonant wave, we would have to conclude that the node for this first peak was within the aortic arch itself. This swell developed at about the same time that the foot of the incident wave reached the femoral artery. Later reciprocal oscillations between ascending aorta and lower abdominal aorta could be seen, with minimal pressure change in the upper thoracic aorta. The node of these oscillations would thus appear to be more distal than that for the systolic peak. All that we can conclude is that the genesis of aortic resonance remains obscure.

Other Factors Which May Alter the Central Pulse Contour

Fascinating as this whole problem of resonance may be, it certainly is not the sole factor which may produce contour change and pulse pressure change when the pulse of the ascending aorta is propagated to the lower aorta or to the brachial artery. Possible factors which may bear on these changes are:

a) A loss of sharp inflections and an attenuation of the pulse pressure might result from damping. In a distensible tube such damping is due in part to fluid friction, but probably much more to a conversion of energy from kinetic to potential form because of the extension of the walls, with a delayed recoverability of this energy because of the visco-elastic properties of the wall. Clear illustrations of such a reduction in pulse pressure and lengthening of the systolic wave contour during propagation can be seen in dogs with a deteriorated circulation, or at least a weakened heart, after the use of a strong vasodilator agent (94) and when the rate of flow from the upper aorta to the lower is severely reduced, as by a partial occlusion (23).

b) A peaking of the pulse contour could follow a

speeding of the upper portions of the pulse as the modulus of extensibility is increased. This would probably cause an augmentation of the pulse pressure. This effect seemingly would be operative only if wall hysteresis were of minimal importance. However, I am not convinced that there is any difference in transit time of the wave foot and of the incisura, for example.

c) The same sort of peaking could indicate an attenuation of mismatched harmonic frequencies. If the electrical analogy is apt, there would be no augmentation of the pulse pressure in this case, however, but simply less attenuation of the matched frequencies. In a hydraulic system, of course, it might be that attenuation of one part of the pulse might yield fluid and energy for another frequency, which conceivably could produce pulse pressure augmentation. Such a redistribution of energy has not been shown to be true.

d) There could be a reflection of the whole or a part of the incident wave, whether the vascular bed did or did not achieve resonance as it has been described. The maximum possible increase in pulse pressure by reflection would be to twice the original value, which would be realized only if the whole pulse pressure showed complete reflection, and the pulse recording was very near the reflection "end" of the system. Usually the pulse pressure in a femoral artery is less than twice that of the central pulse. However, Alexander has shown femoral pulse pressures in the dog which are greater than twice the value.

e) As an extension of d), or perhaps as a result of another property of the bed entirely, when the aorta does show resonance, augmentation of the pulse pressure is appreciably greater than when a standing wave is not seen.

f) In some cases where the cycle length is short, the diastolic pressure swell (presumably the reflected wave) may begin late in the diastolic period. If a new systolic upstroke coincides with the upswing of this swell, very high pulse pressure values can be obtained. This mechanism of augmentation by "superposition" was illustrated by pulses recorded from the system of man (108).

Aside from changes in pulse pressure and the form of the systolic peak, there are other aspects of pulse contour transformation which have no clear explanation. The pulse formed in the ascending aorta shows, after a variable but short period in which the pressure rise from the diastolic level is slow, a rather abrupt assumption of a steep and constant slope of pressure

rise. This anacrotic rise is maintained unchanged for at least 30 msec. It is then usually lost rather abruptly, often with a temporary interruption of pressure rise. This halt is called the shoulder of the pulse. The steeper the preceding slope, the more conspicuous is this shoulder. The rate of anacrotic pressure rise is clearly related to the amount of sympathetic stimulation of the left ventricle, which serves to speed the whole contractile process. Thus, with such stimulation, maximal outflow is reached earlier in systole, the shoulder tends to be at a relatively high pressure level, and the systolic peak of the pulse occurs earlier. A shortening of the length of the ejection period can be used as the basis of an assay method for sympathomimetic stimulation (100). With extreme cardiac stimulation, particularly when the stroke volume is reduced because of inadequate venous return, the shoulder may be so abrupt as to throw the whole aorta into vibrations. Under such circumstances, the height of the shoulder may be greater than that of any other part of the pulse, which makes the shoulder height represent the systolic pressure. In such cases, the pulse pressure may have higher values than would be anticipated from the stroke volume (94), in the peripheral vessels as well as in the ascending aorta.

The slope of pressure rise preceding the shoulder was found by Hamilton & Dow (42) to be propagated unchanged through the aorta. Alexander (4) showed some loss of steepness in the abdominal aorta, while I (99) found it to remain constant in the thoracic aorta and then to steepen in the abdominal aorta. The slope change is never marked, however, so that all three studies are compatible with the general conclusion that this first part of the pressure wave seems to move as an unchanged unit. All three also agree that the steep upstroke continues for a longer time interval the further from the heart the recording is made. This might lead one to the conclusion that this early part of the wave cannot be thought of as being propagated by repetitive accelerations of tiny segment volumes. It was pointed out earlier that the length of what is called a "small segment" of the aorta is undefined. The segment may have an appreciable length, and the volume contained, which is accelerated as a unit, have an appreciable mass. Thus it may be that the propagation of the first part of the pulse wave would involve fluid accelerations which would have many of the physical properties of a volume surge with inertia. If so, one would expect the "surge" to produce a progressively greater pressure rise in the lower regions of the aortic

funnel, where the distensibility is reduced. The speed at which the wave front would move would be dependent in part upon the force of the drive. For under these conditions, the ascending aorta would be "driving" the fluid through the various exit branches, one of which would be the thoracic aorta. These statements are similar to those made previously in the discussion of the relation between the pressure curve and the fluid displacement. It remains for future work to reconcile evidence which seems to favor the presence of a fluid surge with that which supports the proposed model, having wave propagation based on fluid displacement from one tiny vessel segment to the next.

A study of a great number of pulse forms leaves the impression that the volume uptake of the aorta in the period when the pressure shows this initial fast rise is not so large as would be expected from volume-pressure relations taken from a static stretch curve. This impression has not been proven. A rapid pressure rise at a time when the volume input is small was a pillar of the acceleration transient story of Peterson (90). One would like to explain an excess pressure height, if present, on the basis of wall hysteresis. If, in studies with rapid stretches of isolated vessels, there had ever been a considerable overflying of pressure at the end of a stretch, I would feel happier about this possible answer. If the impression is correct that pressure rise exceeds the expected volume gain, then it could also be true that in the interval of the shoulder of the pulse, the volume gain would continue, and thus "catch up" with the pressure.

When the pulse enters either the arm system or the aorta-leg system, the height of the shoulder is increased. In the human arm system, this elevation of the shoulder takes place largely in the subclavian arteries. The brachial pulse then shows two systolic waves, one representing the shoulder, and the other the later systolic part of the entering wave (12, 69, 108) (fig. 13). Very often the first is higher than the second, and hence sets the pulse pressure. This is particularly true when the anacrotic rise formed in the ascending aorta is steep and the shoulder is high. Late in a Valsalva maneuver, for example, the aortic pulse shows a steep anacrotic rise and high shoulder, but the rest of the pulse tends to collapse toward a low incisura. This contour is in keeping with the much reduced stroke volume. But in the brachial pulse the shoulder may remain at almost the normal height, which means that a pulse pressure measured from this height would have no relation to the stroke volume (108).

FIG. 13. Transformation of pulse in subclavian-arm system (subject 1). *A*: arterial pressure pulses recorded at 5-cm intervals during withdrawal of catheter through subclavian-upper brachial system of normal subject. Curve 1 is the aortic pulse, recorded from the thoracic aorta through a catheter inserted via right femoral artery. It has been set back by 0.03 sec. Curve 2 (starting at 0 time) is the pulse in most proximal point in subclavian artery reached by catheter inserted via left radial artery. *B*: continued withdrawal of catheter into lower brachial and radial system. Heavy solid line represents pulse from most proximal position in subclavian (0-cm withdrawal in *A*). The 30-cm withdrawal curve is last pulse from proximal unit (*A*), which still showed the simultaneous initial pressure peak. The 70-cm withdrawal is point at which catheter again entered needle in left radial artery. Pulse from right radial artery, recorded through a similar needle itself, is labeled "radial." [From Remington & Wood (108).]

Conversely, when the pressure is well supported in the upper aorta in late systole, the second wave of the brachial pulse becomes higher, and may then determine the pulse pressure. The maintenance of high, late systolic pressure in the upper aorta may be related to a large stroke volume. Hence in aortic regurgitation, where the ventricle is large and the total stroke volume much increased, the second wave of the brachial pulse becomes quite large. In the aortic pulse, the ejection interval is prolonged and

the systolic peak tends to come late. On the other hand, this maintenance of a high, late systolic pressure may also reflect a change in the acceptance by the aorta of ejected blood. For example, if the aortic pressure is acutely raised, the first result is a reduced stroke volume and a tendency toward shortening of the ejection period. This is presumably because the energy cost of ejection has been raised. As the heart size increases, the stroke volume shows some tendency to increase, and the duration of ejection becomes longer. The systolic peak comes later in systole. This pattern is clearest in animals with chronic hypertension. Part of this change may be due to a change in cardiodynamics (although not documented as such). A more likely explanation is that as the pressure rises, the front of the wave moves more rapidly through the whole receiving arterial reservoir, so that by midsystole the whole reservoir may be so nearly filled that the vessels act more as rigid conduits than as extensible tubes. As discussed previously, this tends to maintain the pressure at higher levels in the ascending aorta.

Conversely, when the aortic pressure is acutely lowered, the first few beats show a prolongation of systolic duration, with the systolic peak remaining in midsystole. After the first few beats, as the heart size becomes smaller, the stroke volume is reduced, and the peak tends to occur earlier (45, 94). At low pressures, the wave front moves so slowly through the reservoir that volume is still being readily accepted by the lower aorta, and hence by the ascending aorta, toward the end of systole.

The location of the systolic peak and the contour of the main part of the systolic portion of the pulse contour depend upon the varying characteristics of both the arterial reservoir and the cardiac ejection curve. This can also be taken to mean that the form of the ejection curve is molded by the rate of aortic acceptance of blood. Hence when the pressure is elevated, and the wave moves more rapidly through the vessels, the whole reservoir is filled in less time. Toward the end of systole, then, cardiac ejection need only compensate for the drainage loss, and the pressure can be held relatively high until ventricular relaxation begins (106). Conversely, when the aortic pressure is lowered and the pulse moves more slowly, the ejection of the same amount of blood will produce a greater rise in pressure in the upper aorta. If the pressure peak is still being propagated into the more distal vessels toward the end of systole, we would expect a fall in pressure in the ascending aorta, for the small amount of cardiac ejection could not

compensate for the fluid displacement required to construct the pulse wave.

The incisural vibration is formed in the ascending aorta and is propagated at an orderly rate not greatly different from that of the wave foot (98, 99). In many cases, and particularly when the systolic peak is reached late in the ejection period, it develops as soon as the ventricular pressure falls below the aortic level. In other cases, an appreciable pressure difference between ventricle and ascending aorta is developed before the notch appears. This is particularly true in pulses which have a high anacrotic shoulder and a collapsing pulse late in systole (98). Valve closure is also delayed when the aortic pressure is low. At times it may not appear until the isometric relaxation phase of the ventricle is almost complete (106).

It may be more than coincidence that the delay of the incisura is seen in those cases where the wave front is still moving through the reservoir. Valve closure must require a certain amount of flow reversal in the ascending aorta. It seems reasonable that this reversal could be accomplished more readily when outflow from the upper aorta is minimal (as with high pressure).

In most normotensive pulses the incisura has been damped out by the time the pulse enters the abdominal aorta. With elevated pressure, it may be seen as far as the femoral artery. With a lowered pressure level, it may be lost in the thoracic aorta. This difference is presumably attributable to the various visco-elastic properties of the wall at the different pressure levels. Whether the incisura is still present or not, the pulse of the lower aorta and the leg arteries shows a deep early diastolic trough. This is accentuated in fever, hyperthyroidism, and aortic regurgitation. Three different factors contribute to the presence and size of this trough. First, it is influenced by the late systolic fall in pressure of the central pulse. Second, the trough contains the remnant of the incisural vibration. Third, the trough appears to be set by the same mechanism that gives rise to the augmentation of the systolic peak, especially when this augmentation appears attributable to the achievement of resonance in the aortic system (2, 7, 99).

The fundamental form of the diastolic part of the pulse is probably the same for all pulses, no matter where recorded, except for the size of the periodic oscillations which are superimposed. Where such oscillations are minor, the slope appears exponential (140), but the relation of the rate of pressure fall to

existing pressure level does not remain constant during a prolonged diastolic period (25). It is difficult to generalize about the factors which contribute to the height of the diastolic oscillations. When the pressure is raised to hypertensive levels, the postincisural hump of the central pulse is usually much less conspicuous. This is due in part to the fact that it is then superimposed upon a part of the pressure curve which falls much more steeply, since the vessel distensibility is decreased in the high pressure range. It is much more probable that the relatively small size of the hump is a result of the fact that it starts near the time of the incisura (or even before), because the propagation velocity of the returning wave is more rapid. Conversely, at low aortic pressures, the postincisural hump of the central pulse may be quite conspicuous. This is partly because the basic diastolic slope is so shallow that any pressure increase is clearly evident, and partly because the frequency of the "resonant" oscillations is decreased, so that the swell comes later in diastole; also, it may be due partly to an actual augmentation of the swell itself.

Calculation of the Stroke Volume From the Central Pressure Pulse

On the theory that the aorta achieved immediate resonance, which means that the time interval between two successive pressure oscillations on all peripheral pulses would be the same and would be an index to the length and distensibility characteristics of the aortic reservoir, Frank (30) regrouped a formula similar to that of Bramwell and Hill to have it express the total distensibility of the whole resonant system. Hence where v is the pulse wave velocity, A the cross-sectional area of the bed, L its length, ρ the specific gravity of blood, and $\Delta P/\Delta V$ the slope characterizing the system distensibility:

$$v^2 = \frac{AL\Delta P}{\rho\Delta V} \quad (21)$$

With the simplifying assumption that $\Delta P/\Delta V$ remains constant throughout the range covered by a given pulse, we can, with extreme reservations, take ΔP to be the recorded pulse pressure, and ΔV the corresponding volume change. This assumes that the V for a given vessel would have a fixed relationship to the volume gain by the whole arterial bed. Rearrangement of the formula gives:

$$\Delta V = \frac{AL\Delta P}{\rho v^2}$$

Since the time interval between successive pressure peaks is assumed to be that required for the pulse wave to make a round trip through the system, $T = 2L/v$, or $L = Tv/2$. Substituting in the formula then gives:

$$\Delta V = \frac{ATv\Delta P}{2\rho v^2} = \frac{AT\Delta P}{2\rho v} \quad (22)$$

German workers have continued to use the Frank formula, or modifications of it. These formulas have received only restricted support in this country (124). While they may, perhaps, predict in reasonable degree the volume input into a rubber tube where the distensibility is uniform through the tube length, their use with the complicated arterial bed requires very large assumptions. First, there is the inference given above that the $\Delta P/\Delta V$ relation for any single vessel is indicative of the relation for the whole reservoir system. Second, A does not represent the area of any single vessel, but rather that of a hypothetical tube which happens to have the same dimensions as the mean of the whole reservoir network. Attempts have been made to take values for A from autopsy data, using the upper aorta, which certainly would not have the same dimensions as this mean. Further, autopsy data give a diameter at near zero pressure and not that at a physiological pressure. Third, since ΔV is the volume stored in the Windkessel during systole, it is not directly measurable. If a calculation is made for the drainage loss during systole (and various formulas have been proposed for calculating this loss), then the stored volume plus the calculated drainage loss would equal the stroke volume, which can be measured directly only under restricted conditions, but which is usually taken from a cardiac output determination. Fourth, L , the length of the reservoir network, cannot be directly measured. As described earlier, it has instead been calculated from the length of the resonant wave, as indicated by the time interval between successive pressure peaks of a peripheral pulse. This, of course, assumes that the reflecting end of the system is also the end of the Windkessel. The estimation of wave velocity and of the time interval between pressure peaks, by the techniques employed, leaves room for doubt as to the validity of any strict quantitation.

If the stroke volume could be directly measured, it might be that the various unknowns could be combined into a single constant. Its value, however, would apply only at the diastolic pressure for which it was derived, only if neither A nor L was subject

to physiological change, and only if a constant so derived for one individual could be applied to another. All these assumptions have seemed so precarious that the German formulas have not received favor in this country.

Yet the hope remains that some means can be devised by which the stroke volume can be predicted from the values of the pressure pulse. This would allow a quantitation of beat-to-beat changes, and also of the acute change in ejection volume that occur as the cardiovascular status is rapidly changed. We have no direct method applicable to closed-chest animals that can measure these stroke volume changes. Until we do, an indirect approach can serve a limited but useful purpose.

Another attempt at making this sort of indirect calculation was made by Bazett and co-workers (10). They divided the arterial reservoir into four parts: 1) the aortic arch and its large branches; 2) the whole of the descending aorta through the iliacs; 3) the subclavian-brachial systems; and 4) the femoral-leg system. They recognized that the pulse pressure would be different in these regions, and therefore concentrated instead on the pressure change taking place during diastole, when the previously stored blood was being discharged through the resistance vessels. They assumed that, by the time of the incisura, the whole arterial reservoir would be draining as a single unit, and that the pressure change could therefore be that from the level of the incisura of a central pulse to the end-diastolic value. Unfortunately, their central pressure pulses were rather inadequately recorded. Next, using calculations based on the size of the larger vessels of each arterial region as taken from autopsy data, and using assumptions and empirical adjustment of the derived diastolic volume values, they arrived at figures for the total diastolic volume for each region. The change in volume from this level was then equated as a function of the pulse wave velocity through the region, or

$$\Delta V = \Delta PK \left(\frac{V_1}{v_1^2} + \frac{V_2}{v_2^2} + \frac{V_3}{v_3^2} + \frac{V_4}{v_4^2} \right)$$

where ΔV is the total stored volume, the V 's are the calculated diastolic volumes of the four parts of the reservoir, and the v 's the respective wave velocities (which could be measured only rather crudely). With more modern technology, the basic data could be much more accurately recorded. The formula would still be rather cumbersome, and the necessary

measurements many. Two of the major weaknesses still present are that V cannot be directly obtained, any more than the A of Frank's equation can be, and that the v values of necessity must be taken from a single large artery in each of the regions. This assumes that this artery can fairly represent the whole system, and also that this velocity gives a true indication of vessel distensibility.

We presented another approach to the problem, worked out on the dog rather than on the human. For reasons which have been covered previously, we regarded the wave velocity as a most dubious measure of vessel distensibility. Instead, we substituted volume-pressure relations taken from data obtained by stretching isolated rings, and by injecting saline into occluded arteries of dead animals. We necessarily assumed that the values obtained would be practically the same for different animals. To make some correction for differences in body size, all values were expressed per square meter of body surface area. We also assumed that the transmission time through the various arterial beds would be the same for all animals, at the same diastolic pressure level. After making the studies described above, in which we calculated the presumed cardiac ejection curve on the basis of a summation of volume uptake values of the arterial regions taken serially as they were invaded by the pulse wave, as described above, we settled on the premise that such a summed total uptake, with a calculated systolic drainage added, should equal the stroke volume at the time of valve closure. Hence we could work with a single central pressure pulse, laying back the transmission time to each of the four major divisions of the arterial bed, from the incisura. The pulse pressure to be quantitated for each bed would then simply be the pressure shown at this interval before valve closure. In other words, the point at which this time interval intercepts the pressure pulse curve indicates the pressure developed in the bed in question at the end of systole. This assumes that there was no change in pulse contour during propagation. More rightly, it assumes that any contour change present during propagation would be constructed by a redistribution of the volume of blood ejected into the ascending aorta to create the given central pressure pulse. Attempted modifications based on actual pulse contours taken at various points in the aorta did not alter the value of the calculated stroke volume to significant degree.

Without introducing any empirical correction factor, the agreement between the predicted and

the stroke volume derived from the dye injection or Fick's procedure was within 12 per cent (44). Further work brought to light two areas of discrepancies. First, the predictions tended to underestimate the actual stroke volumes at high pressure ranges. The volume-pressure values were then empirically adjusted to take care of this (94). The correction used is almost identical to the difference between the single continuous stretch curve of figure 3 and the curve connecting the midpoints of the consecutive loops, which fact suggests that there may be a theoretical foundation for the empirical correction. The second and more serious failure of the method is that it yields a definite overestimation of the actual stroke volume in some shock states in which the pressure shows a brisk anacrotic rise with a high shoulder, but is then poorly sustained later in systole. This type of pulse has been described above. The possible causes of the failure in prediction for these rare pulses were discussed rather fully in a symposium presented in 1952 (86a) and little more light has been shed on the problem since.

- General Rules Relating Murmurs to Nonlaminar Flow
- Normal and Pathological Flow Pulses in Humans

Flow in the Ascending Aorta
Descending Thoracic Aorta
Tricuspid Valve

THE HIGHLY PULSATILE NATURE of the blood flow in both the systemic and pulmonary circuits primarily arises from the intermittent action of the heart as a pump. Each ventricle has a valve at its exit and entrance such that the blood flow and velocity oscillate from near zero, when the valves are closed, to relatively great values during the time when the valves are open. Great changes in the velocity arise from the starting and stopping of the blood stream with the opening and closure of these valves. Secondary causes of flow pulsations, particularly in the veins, arise from the respiratory fluctuations and muscular contractions.

I. METHODS OF MEASUREMENT

Methods for the detection of blood flow and pressure oscillations within this system require a frequency response flat to at least 100 cps and without phase shift. Present day pressure systems achieve this ideal quite well if one does not introduce long elastic catheters between the pressure tap and the transducer. Present day blood flowmeters, however, have not achieved this degree of perfection, but recently great progress has been made. In addition to the frequency and phase characteristics mentioned, a blood flowmeter should be capable of detecting the blood flow or

velocity from either the surface of a surgically exposed vessel or by means of a catheter tip introduced into the flow stream, but without causing significant distortion of the flow dynamics.

All the blood flow recordings gathered by the authors for this chapter, if not otherwise indicated, have been made with a 240-cycle square-wave electromagnetic flowmeter (11) introduced in 1953 as the first practical instrument for measuring blood flow in any of the body's arteries and veins which have been surgically exposed. As used here, this instrument has a flat frequency response to 40 cps, and is down by 50 per cent at 100 cps, and, although the principle is capable of an infinite frequency response, these limitations are necessary in a practical instrument primarily because of the carrier frequency residual which would otherwise appear on the flow record. The magnetic probes applied to the blood vessels restrict pulsations and encroach on the lumen to the extent of reduction in cross-sectional area by approximately 5 to 10 per cent. Such slight constriction assures firm contact of the electrodes to the arterial wall. Experimental testing showed that this amount of constriction caused no perceptible change in the recorded flow pulse (45).

Properties and Principles of Flowmeters

For recording of vascular flow velocity pulses an ideal flowmeter should possess several properties: a linear response to forward and backward flows, a stable zero reference, and a frequency response adequate to follow the phasic phenomena being recorded. It should also be unaffected by nonrelated phenomena such as blood pressure, internal noise, and muscle action potentials. Furthermore, its operation should not modify the phasic flow patterns, mean flows, or blood pressure. To meet this last requirement completely would mean that not only must the blood vessel under consideration be unobstructed and non-cannulated, but also that the recording be done without anticoagulants or anesthesia and without psychic trauma to the experimental subject (59).

Obviously, a practical flow-recording system requires some compromise with the above ideals; also, such an elegant device would not be necessary for most research work. If one knows the general character of the quantities to be recorded, he may use with confidence an equipment the characteristics of which are considerably more restricted than the ideal. For instance, a frequency response of zero to 50 cps is felt to be adequate for cardiovascular work (6, 46); also,

when recording ascending aorta flow, zero drift is not serious since the flow can be taken to be zero at the end of diastole, thus giving a continuously repeated zero check. Therefore, an instrument used for cardiac output measurements may have considerable drift of zero and still be satisfactory for the purpose if it meets the other requirements, although it might be unsatisfactory for other situations where a stable zero reference is essential (14).

Many different principles have been used for flow recording; all have inherent potentialities for errors in application or interpretation. These principles and the instruments which embody them are discussed in detail in Chapter 38. Here it will be necessary only to list the different types of instrument and certain references to the literature which are not found elsewhere either in this chapter or in Chapter 38.

a) Electromagnetic flowmeters (1, 3, 5, 8, 9, 16, 24, 53, 57, 63). b) Ultrasonic flowmeters (25). c) Nuclear magnetic resonance (4, 23). d) Pendulum or bristle flowmeters. e) Catheter tip pickups (36, 38). f) Turbinometers (40, 41). g) Differential pressure flowmeters (10, 17, 39).

Cognate Phenomena

LATERAL AND DIFFERENTIAL PRESSURES. In any critical study of the relationship of the dynamics of pulsatile flow it is necessary that pressure and flow be measured simultaneously, and that the pressure be picked up from a pressure tap the orifice perimeter of which is in a plane parallel to the flow stream. One highly practical system is to use a "clip needle" which by means of a flexible clip holds the end of the needle against the inside of the blood vessel wall (49). If a Huber point is used on the clip needle, the recorded pressure can be a true lateral pressure.

The use of differential pressure measurements has greatly enhanced our interpretation of the phenomena occurring simultaneously within the vascular system. Such a method usually takes the form of two pressure taps conducted separately to either a differential pressure transducer or to two individual pressure transducers the amplified signals of which are electrically subtracted from one another continuously. The latter system has the advantage of being able to view the individual pressures which make up the differential pressure recording. These individual recordings are useful in identifying artifacts which may arise.

COMPUTER TECHNIQUES. For a proper understanding of the hemodynamics of the cardiovascular system, a full

appreciation should be had for the relationship between flow velocity, volume, and displacement. These relationships may be expressed best by means of calculus symbology, as follows:

$$\begin{aligned}\text{Displacement (cm)} &= \int_0^t \text{Velocity (cm/sec)} dt \\ \text{Velocity (cm/sec)} &= \int_0^t \text{Acceleration (cm/sec}^2\text{), } dt \text{ and} \\ \text{Volume (cm}^3\text{)} &= \int_0^t \text{Flow (cm}^3\text{/sec)} dt \\ \text{Flow (cm}^3\text{/sec)} &= \int_0^t \text{Volume acceleration (cm}^3\text{/sec}^2\text{)} dt\end{aligned}$$

For example, the cardiometer tracings during the systolic ejection period may be said to be the negative integral of flow through the aortic and pulmonary valves, and the diastolic cardiometer tracing is the integral of the flow through the A-V valves. Also, the radial displacement of the arteries and veins may be said to be the integral of the radial velocity of blood flow within the lumen.

Analogue computer techniques, useful in the study of vascular hemodynamics (50), allow one to move from volume to flow to acceleration by means of integration, or the reverse, through differentiation. Two types of integration are currently in use: 1) the true time integral which is an instantaneous sum of a given function, beginning from any given time; and 2) damping or "meaning," an older usage of the word which implies a mean value of a periodic function. Damping may be accomplished either mechanically or electrically. The most practical way to perform this mechanically in a pressure recording system is to introduce compliance or resistance into the transmitting system, e.g., by means of a bubble in the gauge or a partial occlusion clamp on the catheter tubing. Damping in an electrical system amounts to a fully charged integrating circuit in which the rate of current inflow into the integrator over one pulse cycle equals the rate of current outflow.

II. ELEMENTS OF VASCULAR HYDRAULICS

The arterial system is a many-branched elastic conduit for distribution of blood from the heart to all body tissues. The caliber ranges from 35 mm for the human aorta to 7 μ for the capillaries. Over this wide range each vascular segment may be described by three fundamental physical properties: resistance, inertance, and compliance.

Resistance (R)

This arises from the friction between shearing molecules flowing through the segment. Expressed in terms of the pressure difference (15) across the resistance, ΔP_R , in dynes per square centimeter¹; the blood velocity, u , in centimeters per second; the cross-sectional area, A , in square centimeters; and the flow ($F_R = uA$), in cubic centimeters per second,

$$R = \frac{\Delta P_R}{u \cdot A} = \frac{\Delta P_R}{F_R} \quad (1)$$

After Poiseuille, in terms of vessel dimensions, length (l) in centimeters, radius (r) in centimeters, and blood viscosity (η) in dynes · second per square centimeter,

$$R = \frac{8\eta l}{\pi r^4} \quad (2)$$

The vessel wall also has a small resistance opposing radial distention and collapse. The inverse of resistance or conductance ($1/R$) is often a useful term. The symbol for hydraulic and viscous resistance is taken from electronics (WW).

Inertance (L)

This resides primarily as the mass of blood and secondarily as the mass of the arterial wall. It is expressed in terms of acceleration (a), and attendant pressure difference across the inertance, ΔP_L , in dynes per square centimeter.

$$L = \frac{\Delta P_L}{a \cdot A} = \frac{\Delta P_L}{dF_L/dt} \quad (3)$$

where F_L is the flow through the inertance, and where $L = m/A^2$, m is the mass of the blood in the segment of artery under consideration expressed in grams, and A is the cross-sectional area in square centimeters. In terms of vessel dimensions (55), l and r , in centimeters and blood density (ρ_B) in grams per cubic centimeter,

$$L = \frac{\rho_B l}{\pi r^2} \quad (4)$$

¹ Pressure in dynes per square centimeter should be used instead of the conventional pressure in millimeters of mercury. The following expression is used to convert from millimeters of mercury (h) to pressure in dynes per square centimeter (P):

$$P = 0.1 \text{ g } \rho_{Hg} h = 1323 \times \text{mm Hg}$$

where g is the acceleration of gravity in cm/sec², and ρ_{Hg} is the

The symbol for inductance is that for electrical inductance ($\text{---}\text{---}\text{---}$). Because inductance is defined in terms of volumetric acceleration, the larger the cross section of the vessel lumen, the smaller is the inductance in a vessel of given length.

Compliance (C)

Compliance is a property of the arterial wall arising from its distensibility and chiefly residing in the elastic fibers. The contribution of smooth muscle and fibrous tissue has not been determined. It is expressed in terms of blood volume (V) in the segment and the attending pressure difference across the vascular wall ΔP_c .

$$C = \frac{V}{\Delta P_c} = \frac{1}{\Delta P_c} \int F_c dt \quad (5)$$

where F_c is the flow into the compliance, or in terms of dimensions (22) length (l), radius (r), wall thickness (o), and the modulus of elasticity (E):

$$C = \frac{2\pi r^3}{Eo \cdot l} \quad (6)$$

The symbol for compliance is that of electrical capacitance ($\text{---}\text{---}\text{---}$).

Axial Flow

In a segment of rigid pipe axial flow is analogous to the current in the diagram of figure 1. Where $\Delta P_{\text{axial}} = P_1 - P_2$, ΔP_a at any instant in time will be equal to the sum of the pressure differences due to the R and L components. Thus:

$$\Delta P_{\text{axial}} = \Delta P_{\text{Resistance}} + \Delta P_{\text{Inductance}} \quad (7)$$

(Any pressure gradient resulting from gravity cancels if the pressures are referred to the same level.) Substituting from equations 1 and 3, and considering $F_R = F_L = F$,

$$\Delta P_o = RF + L \frac{dF}{dt} \quad (8)$$

integrating with respect to time we have

$$F = \frac{1}{L} \int (\Delta P_o - RF) dt \quad (9)$$

This equation may be solved continuously by an analogue computer and has some practical applica-

density of mercury at the existing experimental conditions in g/cm³.

FIG. 1. Electrical analogue of axial flow and pressure in a rigid tube.

FIG. 2. Electrical analogue of radial flow in an elastic tube.

tion in the ascending aorta (12, 13). The procedure is to subtract P_2 from P_1 to obtain ΔP , and then to subtract RF from ΔP and integrate the result. If $1/L$ is known or is chosen arbitrarily, R may then be adjusted until F achieves some known boundary condition such as $F = 0$ during diastole. Figure 3B graphically illustrates the procedure. If accurate values for vessel dimensions, blood density, and viscosity are available to calculate L and R , the result can be obtained in terms of actual flow in cubic centimeters per second, otherwise the answer only yields the velocity in centimeters per second.

Radial Flow

In a visco-elastic artery, radial flow is analogous to the current in the diagram of figure 2.

$$\Delta P_{\text{radial}} = \Delta P_c + \Delta P_R \quad (10)$$

where ΔP_{radial} represents the pressure difference across the arterial wall ($P_{r1} - P_{r2}$). Substituting from equations 1 and 5, where $F_r = F_c = F_R$,

$$\Delta P_r = \frac{1}{C} \int F dt + RF \quad (11)$$

and differentiating,

$$F = C \left[\frac{d\Delta P_r}{dt} - R \frac{dF}{dt} \right] \quad (12)$$

or rearranging equation 11

$$F = \frac{1}{R} \left[\Delta P_r - \frac{1}{C} \int F dt \right] \quad (13)$$

Since measurements of pressure and vessel diameter are very similar, friction within the arterial wall and radial inertance are apparently quite small, although in the final analysis, as clearly indicated by Peterson (35), one must consider acceleration along with distensibility and friction.

When the total flow (F_T) in an elastic pipe is considered, both radial and axial flow equations must be combined as follows for instantaneous flow: $F_T = F_{axial} + F_{radial}$, and, from equations 9 and 12,

$$F_T = \frac{1}{L} \int (\Delta P_o - R_o F_o) dt + C \left[\frac{dP_r}{dt} - R_r \frac{dF_r}{dt} \right] \quad (14)$$

In analogue computer language this equation is solved as in figure 3. Patel *et al.* (33) have found negligible degrees of inertance and resistance in the pulmonary artery wall.

A more complete hydraulic diagram of an arterial segment may be well shown as in figure 4. L_1 , R_1 , and C_1 represent its most important elements, with R_2 and R_3 representing radial and axial resistance, and C_2 representing axial compliance. The complete arterial system may be viewed as a continuous linkage of such segments, each branch and segment having quantitative differences in magnitude of the individual physical elements. At the same time, the physical elements of any segment or group of segments may be described by over-all "lumping" of the elements.

The arterial system is not a passive network because the elements may be influenced by the nervous system, endocrine system, metabolic processes in the wall, and changes in the physical properties of the blood. In addition, the values of the elements are nonlinear functions of pressure, vascular dimensions, velocity profile and many other influences. In spite of these complications, much can be learned by linear analysis of the pressure and flow pulses at various

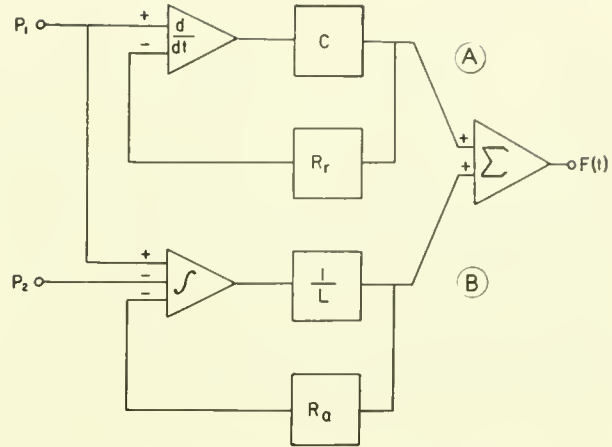

FIG. 3. Analogue computer diagram for solution of the equation of liquid flow in an elastic tube. P_1 and P_2 represent the lateral pressures from two stream points. ΔP is the independent variable ($\Delta P = P_1 - P_2$).

FIG. 4. Elaborate electrical analogy of a vascular segment.

points within the arterial network studied under reasonably steady-state conditions.

Hydraulic Impedance

This is the concept of total opposition to pulsating and constant flow. Drawing on the electrical symbolism, we have Z , X_L , X_C , and X_R , where Z represents the total impedance, and X_L , X_C , and X_R equal the inertial, compliant, and resistive impedances. X_R is the opposition to flow, X_L is the opposition to change in flow, and X_C is the opposition to change in volume. Both

X_L and X_C depend on the frequency (ν) as follows:

$$X_L = 2\pi\nu L \quad X_C = \frac{1}{2\pi\nu C}$$

The impedance to blood flow through L and C elements will therefore be expected to be frequency dependent, and may be termed hydraulic reactance in contradistinction to resistance which is not frequency dependent. Hydraulic impedance may be expressed as dP/dF , i.e., the rate of change of pressure with respect to simultaneous rate of change of flow. On a pressure-flow diagram, impedance would be represented by the tangent to the curve at any given time.

Flow Source Versus Pressure Source

The impedance or "stiffness" of the flow source and pressure source may be expected to influence the response of a vascular segment. For example, a small branch, such as a renal artery arising directly from the aorta, is fed by a stiff pressure source, inasmuch as great changes in renal vascular impedance encountered within extreme physiological ranges have no effect on the abdominal aorta pressure.

On the other hand, the left ventricle without external controls behaves as a flow source because relatively great changes in systemic arterial impedances (viz., aortic stenosis, hypertension, vasodilation) cause small changes in the cardiac output. On a beat-to-beat basis, therefore, the left ventricle may be considered to be a stiff flow source or volume pump, and the response of the arterial system is greatly influenced by this fact. The performance of the left ventricle as a volume pump is illustrated in figure 5. The carotid sinus feedback loop tends to make the heart rate and strength of contraction vary inversely with the arterial pressure, but requires several beats for its correcting action. Hormonal negative feedback loops also act on the heart to cause it to perform as a stiff pressure source, but act even more slowly than the reflexes.

The Analogy Approach

This is: *a*) to diagram an electrical network model of specific segments of the arterial system based on qualitative facts available from physiology by identifying blood pressure and blood flow with electrical voltage and current; *b*) to test the model against conditions in an experimental animal by pulsing a direct analogue or an analogue computer with electrical voltage or current transduced from the

FIG. 5. Response of the dog's left ventricle to sudden increase in outflow resistance caused by partial occlusion of the ascending aorta. — Control; ---- moderate obstruction; severe obstruction.

blood pressure or flow. The computer is programmed to solve the equation of the electrical network, but in this case in terms of pressure and flow instead of voltage and current. Several general considerations of the analogue approach are available (32, 34, 54, 60).

Considerations of this section approach the vascular system from the standpoint of a transient response as distinguished from the usual use of steady-state oscillation in which the harmonic content must be known to reach a solution (20, 26, 51, 61, 62). The transient response method has the advantage of giving an instantaneous solution while in addition each term of the equation has physiological meaning. To regard the arterial pulse as a steady-state oscillation is to fail to recognize the input pulse and the response of the vessels as two independent phenomena

and overemphasize the regularity of the heart rate. Also, the terms of a series such as the Fourier have no real physiologic meaning and in fact may fail to show a dominant and important frequency such as the arterial resonant wave.

III. SYSTEMIC ARTERIAL FLOW

Shipley *et al.* (44) and Pritchard *et al.* (37) made one of the most comprehensive recordings of the arterial flow pulses using the differential pressure flowmeter. They offered no fundamental theory to explain the recorded phasic pressure-flow relationship. Although some exception may be taken to their flowmeter, the general form of the flow pulses agrees well with more recent electromagnetic noncannulating recordings.

Blood Flow in the Ascending Aorta

The arterial network is pulsed by a flow pulse from the left ventricle normally of the configuration in figure 6. This recording is taken with the square-wave electromagnetic flowmeter on the ascending aorta, 3 to 5 cm distal to the aortic valve. What were apparently the first accurate phasic recordings were made by Wetterer (58). The linear acceleration of the blood by the left ventricle is remarkable, reaching greater than 8000 cm per sec per sec in an anesthetized open-chest dog (47). At the end of acceleration, the velocity of the blood in the ascending aorta may easily exceed 100 cm per sec in the resting state. Deceleration takes place at a rate approximately one-sixth of acceleration until closure of the aortic valve when a sharp notch of deceleration and acceleration brings the flow to nearly zero for the duration of diastole.

For many practical purposes this flat "uneventful" tracing during diastole in the ascending aorta may be used as a zero flow reference to compute the stroke volume. The fact that coronary flow is not included may produce a small unknown error. Apparently, the diastolic flow curve in the ascending aorta is flat at nearly zero because the reversing effect of coronary flow is balanced by the forward effect of decompression of the first portion of the ascending aorta. The left ventricular ejection velocity at the root of the aorta recorded by Pieper (fig. 7) is similar to the flow pulse throughout the ascending aorta. Since this instrument records the axial velocity, it appears that the velocity profile of the ascending aorta is relatively

FIG. 6. Flow pulses in the ascending aorta of an unanesthetized dog. C-core electromagnetic probe was implanted 6 weeks prior to this record on the ascending aorta. Electrical connections were made by means of implanted subcutaneous wires, brought to the surface through a small superficial incision.

FIG. 7. Axial flow pulse in the ascending aorta recorded by means of velocity probe situated in midstream. [From Pieper (36).]

flat. More backflow occurs here during early diastole presumably because of diastolic coronary flow.

The effect of exercise on the ventricular ejection pulse is illustrated by a remarkable experiment by Olmsted (personal communication), figure 8. The animal had a magnetic probe implanted on the ascending aorta and an arrangement for remote pressure recording. After one month's recovery from the surgical procedure he was exercised by running in a harness behind a station wagon carrying recording equipment. Suitable wiring carried the electrical signals between the automobile and the dog. The course was one-half mile over rough terrain at an average speed of 10 mph. Upon standing, the cardiac output increased primarily because of increased heart rate without change in stroke volume and with little change in form of the ejection pulse. Running at 5 mph increased cardiac output by increasing both

FIG. 8. Effect of exercise on blood flow in the ascending aorta of a trained dog. See table 1 and text. (From Olmsted, personal communication.)
1 = lying, 2 = standing, 3 = 5 mph, 4 = 8 mph, 5 = 10 mph, 6 = hill, 7 = $\frac{1}{2}$ mile point.

TABLE 1. *Ascending Aorta Flow During Exercise*

| Exercise | Elapsed Time, Sec | Cardiac Output Liter/min | Blood Pressure (Arch) | Stroke Volume, ml | Heart Rate/min |
|-----------------|-------------------|--------------------------|-----------------------|-------------------|----------------|
| Lying | 0 | 2.9 | 139/86 | 25 | 113 |
| Standing | 0 | 3.5 | 122/73 | 25 | 140 |
| 5 mph | 18 | 5.6 | 86 | 28 | 200 |
| 8 mph | 25 | 6.2 | 81 | 31 | 200 |
| 10 mph | 55 | 6.0 | 79 | 28 | 214 |

| Half mile | 180 | 6.6 | 98 | 33 | 200 |

* 40% above control.

heart rate and stroke volume. Further effort increased output primarily by increasing the stroke volume with little change in heart rate. The increase in stroke volume was evidenced by a change in the contour of the ejection pulse from its normal triangular shape toward that of a square wave. The failure to increase greatly the peak velocity may have been due to turbulence impedance or to a limit in the rate of ventricular contraction. As a result of the limiting factor on peak velocity, the animal may have been near his maximum cardiac output. Table 1 gives the flow and pressure values for figure 8.

Pressure-Flow Relationship in the Ascending Aorta

Figure 9 illustrates the instantaneous pressure difference (ΔP) along 3 cm of the ascending aorta with the axial flow through the same segment. ΔP deflections lead the flow deflections by approximately 90 degrees, which suggests that mass-acceleration laws dominate. A very close approximation of actual flow may be computed from ΔP using equations 5 and 9. In this situation radial flow is small compared to axial flow, thus absence of the radial flow term seems unimportant especially when only the net axial flow is desired.

Fry (13) originally pointed out this relationship and its practical use in a catheter-tip flowmeter. Assuming that the flow profile in the ascending aorta is flat, one would theoretically need only the cross-sectional area of the ascending aorta to compute cardiac output from the pressure gradient. The application of this principle using a double lumen catheter is at the moment fraught with many practical difficulties, primarily concerning Pitot effects at the catheter tip and accurate measurement of the lumen cross section.

Ventricular Ejection Gradients

Because of mass-acceleration effects, ventricular ejection during the deceleration phases takes place against

the pressure gradient (47). Figure 10 demonstrates this fact at the aortic valve where, during late systole blood is flowing through the valve against a pressure gradient. A similar finding has been shown for the right ventricle (H. Okino, unpublished work). These findings prove dynamically that the forward resistance of the aortic and pulmonary valves is slight. Further, the energy of external work of the ventricles is spent in raising the blood pressure to sufficient level to accelerate the blood into the aorta and pulmonary artery.

Windkessel Model of the Arterial System

This has been a concept of limited usefulness to explain the form of the arterial pulses. It may be represented by the analogue of figure 11. The arterial chamber is represented by the compliance (C), and the peripheral resistance by the resistance term (R). The basic relationship here, between pressure and

flow, is $F = C(dP/dt) + (1/R)P$. When this electrical model is experimentally pulsed by a current transduced from the flow in the ascending aorta (F), the voltage form (P) is obtained. By comparison, the actual pressure pulse in the aortic arch (P) deviates in several details from P : 1) P has a superimposed 3 to 6 cps oscillation apparent from midsystole throughout diastole, and 2) P has a more prominent "incisura" marking aortic valve closure and a more abrupt rise, often with an anacrotic wave. In addition, the windkessel model fails to explain the changes in form occurring along the arterial network. Detail 2 appears if the analogy is elaborated by the placement of some restraint on the distensible element, i.e., taking into consideration the friction in lateral expansion of the arterial wall, as in equations 12 and 13. Detail 1 requires a concept of reflections or resonant network filter as explained in the succeeding paragraphs. Cope (7) has attempted new use of the windkessel concept using empirical constants.

FIG. 9. Computer solution to blood flow in the ascending aorta using the analogue computer of fig. 3. F_{emf} = the flow measured by the electromagnetic flowmeter. F_t = computed flow. $C(dP/dt)$ = the radial flow pattern derived from the time differential of the aortic arch pressure P .

Aortic Transformation of Flow and Pressure Pulses

Figure 12 illustrates the changes in form and magnitude of the flow pulses between the ascending aorta and the abdominal aorta. The flow in the descending thoracic aorta represents an intermediary form and well illustrates the superimposition of a prominent smooth 3 to 6 cps wave decreasing in amplitude throughout diastole. This wave referred to as the "resonant" wave frequently causes backflow in diastole throughout the aorta and many of its branches. Considered as a whole, the arterial system is a low-pass filtered hydraulic supply, i.e., it is designed to offer negligible impedance to steady flow and frequencies up to 10 cps. There is normally one frequency between 3 and 6 cps to which it offers lowest impedance, and resonates at that frequency with each beat of the heart. Early physiological workers recognized this resonant system as analogous to a low-frequency underdamped manometer system.

Resonant-Network Model of the Arterial System

This represents an improved concept to explain the transformation of arterial pressures and flow pulses. It is diagramed in figure 13. C_1 roughly represents the lumped compliance of the aortic arch and its branches, and C_2 , the lumped compliance of the abdominal aorta and its branches. L represents the lumped inertance of the blood in the descending aorta. F_H represents the forcing function of the left

FIG. 10. Relationship between the differential pressure and flow through the normal aortic valve. The ordinates refer to the tops of these simultaneous tracings. ΔP = left ventricular pressure (LVP) minus ascending aorta pressure (AAP). The pressure gradient is against the direction of flow in the latter part of systole.

ventricular ejection pulse. R_1 and R_2 represent peripheral resistances which may be adjusted relative to C_1 and C_2 to give any desired ratio of pulse pressure to mean pressure at P_1 .

C_1 , C_2 , and L form a series resonant circuit and may be adjusted to give any resonant frequency, and R_3 and R_4 are chosen to provide the proper damping ratio of the observed resonant wave in the arterial system, as well as the high frequency details. When C_2 is smaller than C_1 , the P_2 pulse pressure is greater than P_1 pulse pressure, thus explaining a time-honored observation that the arterial pressure in the legs rises higher than in the arms during systole.

Figure 14 demonstrates the degree of accuracy with which such a grossly lumped electronic model may reproduce the observed set of pressure and flow values in the arterial network. The resonant-network model embodies several concepts which provide a rational explanation of the major hydraulic features of the arterial system.

1) The over-all frequency response characteristics of the arterial system may be taken as that of an analogous filter network (56), figure 15.

2) The resonant frequency (ν_n) varies from 2 to 10 cps and is increased by hypertension produced by increased cardiac output and sympathetic constrictor agents. It is also increased in cardiac failure due to mitral stenosis. Hypotension from decreased

FIG. 11. Electrical analogue of the windkessel model of the arterial system with experimental testing. P represents the pressure in the aortic arch. V represents the voltage across the parallel resistor and condenser. F represents the measured blood flow in the ascending aorta and the electrical input current forcing the analogy.

FIG. 12. Transformation of the aortic blood flow between the ascending aorta and abdominal aorta. High frequencies are attenuated and a resonant frequency is superimposed.

cardiac output decreases the resonant frequency. Presumably the over-all compliance changes more than the inertance in these conditions.

3) The amplitude of the resonant wave is increased when, in tachycardia, the systolic flow pulse is in phase (48) with the resonant wave.

4) The pressures and movements in the arterial system represent, at any steady state of the hormonal and nervous controlling conditions, transient responses to the flow input from the left ventricle.

5) The augmentation of the pressure pulse, as it is transmitted to the abdominal aorta, results from the lower gross compliance of the abdominal arterial bed as compared to the aortic arch vascular bed.

TABLE 2. *Distribution of Arterial Flow Pulse*

| Artery | Circumference, cm | Mean Peak Flow, ml/min | Mean Peak Velocity | |
|---------------------------|-------------------|------------------------|--------------------|--------|
| | | | cm/min | cm/sec |
| Ascending aorta | 6.28 | 11,870 | 3,780 | 63 |
| Descending thoracic aorta | 5.0 | 3,243 | 1,621.5 | 27 |
| Abdominal aorta | 3.4 | 1,108 | 1,256.2 | 21 |
| Iliac | 1.8 | 750 | 1,429 | 23 |
| Femoral | 0.7 | 182 | 3,275 | 54.6 |
| Renal | 1.4 | 176 | 2,045 | 34.1 |
| Carotid | 1.5 | 193 | 1,401 | 23.4 |
| Brachial | 0.7 | 94 | 1,162 | 19.4 |

6) The 30–100 cps components prominent in the central aortic pressure pulse, as in the anacrotic wave and the incisura, result from the stiffness of the arterial walls and are damped out as they proceed away from the heart. The dicrotic wave so prominent in the peripheral pulse does not arise from this source but is an expression of the resonant wave phenomenon.

Transmission Line Model (Distributed System)

This is a useful concept in the arterial system, as in any hydraulic continuum. It is represented by van der Tweel (55) in figure 16. No matter how short or how long a given segment may be, there is always present some combination of inertance, compliance, and resistance which may be lumped in a close approximation of the behavior of that particular segment.

The performance of the transmission line is greatly affected by the relation of the terminating impedance to the characteristic impedance (52) of the line. If the terminal impedance is equal to the characteristic impedance all the energy will be absorbed and no reflections occur. The characteristic impedance, however, is frequency dependent, increasing with frequency. If the terminal Z is greater than the line Z , positive reflections will occur. Negative reflections will occur if the terminal Z is less than the characteristic Z .

Distribution of the Blood in the Aortic Arch

This is shown in figure 17. In a manner analogous to Kirchhoff's current law, the flow into the arch at any given instant from the ascending aorta is equal to the sum of the flows into the brachiocephalic and left subclavian arteries, and the flow into the descending thoracic aorta plus the uptake rate of the

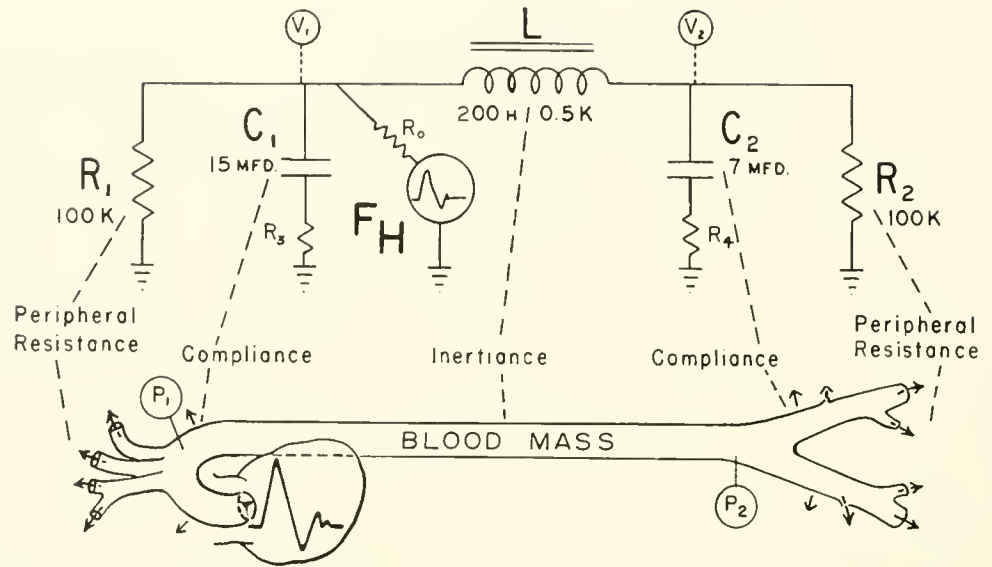

FIG. 13. The resonant network model of the arterial system. Component values indicated are those found in one typical experiment on an anesthetized open-chest dog.

FIG. 14. Experimental testing of the resonant network model of the arterial system. P_1 = pressure in the aortic arch, P_2 = pressure in the femoral artery, F = flow in the ascending aorta, V_1 = the voltage across the capacitor C_1 to ground, V_2 = the voltage across the capacitor C_2 to ground. In the first panel the values of C_1 and C_2 have been adjusted to give the correct resonant frequency as represented in the arterial pulses. Between the first and second panels, R_4 was adjusted to give the proper damping ratio of the series resonant elements C_1 , C_2 , and L . The third panel shows the closest equivalent achieved by adjusting R_3 to reduplicate in V_1 the high components of P_1 . Delay in transmission time is not present because the simplicity of the analogue limited the number of L-C-R transmission line segments.

FIG. 15. Transfer function of the arteries computed by Warner (56). ν_n is equal to a resonant frequency.

FIG. 16. Transmission line model of the arterial system, showing the stacking of L-C transmission line segments. [From van der Tweel (55).]

compliance of the arch (C_{AA}), or

$$F_{AA} = F_{Brach.} + F_{Subcl.} + F_{DTA} + C_{AA} \frac{dP}{dt} \quad (15)$$

figure 17 demonstrates this fact experimentally by comparing a plot of the instantaneous sums of $F_{Brach.}$, $F_{DTA.}$, $F_{Subcl.}$, and $C_{AA} (dP/dt)$ to F_{AA} . The value of C_{AA} was adjusted arbitrarily.

Abdominal Aorta and Its Terminal Branches

By the time the pressure and flow pulses reach the abdominal aorta, the highest frequency components are so attenuated that the flow pulses are dominated by a strong resonant wave superimposed on the mean forward flow (fig. 18). The resonant flow wave in the abdominal aorta is in phase with that in the descending thoracic and the resonant pressure wave [standing wave of Hamilton & Dow (21)] of the abdominal aorta is 180 degrees out of phase with

FIG. 17. Distribution of blood flow in the aortic arch in a manner analogous to Kirchhoff's current law. It is shown that the volumetric flow of blood into the arch of the aorta is equal to the sum of the instantaneous flows into the subclavian artery, brachiocephalic artery, descending thoracic aorta, and the radial flow uptake in the aortic arch. The dotted line in the lower section illustrates the branch outflows (not including radial flow).

that in the upper aorta (48). These phase relationships are similar to those of the series resonant circuit of figure 13. When the resonant flow wave reaches a maximum moving down the aorta, the attending pressure wave in the arch is falling most rapidly. When the resonant flow wave reverses, and flows at maximal rate headward in the aorta, the pressure falls rapidly in the lower aorta while it rises rapidly in the arch. There is a nodal area in the descending thoracic aorta where the pressure wave is minimal (2) and the flow wave is maximal. These findings support the resonant-network model of the arterial system.

Figure 18 demonstrates the remarkable simul-

FIG. 18. Blood flow in the aortic branches. All flow ordinates are scaled equally. The contours of the various flow pulses here may be considered characteristic of the flow in the indicated branches. Carotid flow and renal flow characteristically pulsate around a mean value representing considerable continuous forward velocity. Blood flow in the femoral artery, iliac artery, abdominal artery, and brachial artery may, in the resting condition, oscillate through zero in early diastole but are also, under the conditions of muscular exercise, or metabolic demands, or vasodilator drugs, raised to a level corresponding to considerable mean forward velocity.

taneity of the peaks and troughs of the abdominal and descending thoracic aorta, iliac, and femoral flow pulses. The time of the initial rise is delayed according to the transmission time between the two points under comparison.

Function of the Resonant Wave

The finding of a large backflow component to the flow wave in the descending aorta and vessels of the extremities is at first surprising when viewed from the point of efficiency needs of the circulation. This finding, however, observed in the resting state of dogs (31), sheep (F. C. Greiss, unpublished observations), and in humans (48), disappears upon exercise of the extremities as the muscle vascular beds dilate to accommodate a greater flow.

The normal terminal impedance (peripheral resistance) of the arterial transmission line is apparently greater than the characteristic impedance during the resting state. The vasodilator mechanisms of exercise bring the terminal impedance down to and below that of the line, thereby eliminating positive reflections. Negative reflections do not arise because they are damped out by the resistance of the larger channels made more effective by increased flow. The circulation is thus brought up to more efficient operating conditions when the demands are increased. All the pulse energy passing to the periphery is completely absorbed without reflections when the peripheral resistance is decreased by exercise, injection of vasodilator drugs, and in peripheral A-V fistulas. Figure 19 illustrates the action of lowered terminal impedance in increasing the more efficient transfer of energy. Reflection from the bed beyond, seen in the control blood flow of a small artery in the dog's paw, disappears under vasodilation conditions caused by an intra-arterial injection of acetylcholine. The resonant flow wave disappears and the flow is a simpler function of the arterial pressure. Okino [see (42)] has also recorded these changes.

Renal Blood Flow

The renal vascular circuit may be, as a first approximation, compared to a simple parallel RC circuit (30). The dominant hydraulic elements of the renal artery flow are resistance and compliance, and the equation relating abdominal aorta pressure (P_1), and renal artery flow (F) is:

$$F = C \frac{dP}{dt} + \frac{1}{R} P + K \quad (16)$$

FIG. 19. Blood flow in a small peripheral artery and the effect of vasodilation. According to the definitions of the text, the control flow may be considered a resonant flow form which is converted to resistant flow form by the injection of acetylcholine into the arterial channel. *AP* represents the arterial pressure, immediately proximal to the flowmeter probe applied to a small artery in the dog's paw. *VP* represents the venous pressure in a small vein of the dog's paw. Conversion of the flow from resonant flow to resistant flow by the action of acetylcholine lowers the arterial pressure and raises the venous pressure. (Tracings, courtesy of M. C. Conrad and H. D. Green.)

$1/R$ represents the conductance at the existing pressure, and K represents the fact that the pressure-resistive-flow relationship (excluding the dynamic compliant flow term, $C(dP/dt)$), is not constant and is a nonlinear function of pressure. Presumably this results from the fact that $1/R$ is directly dependent on the pressure in a manner similar to that shown by the vascular beds of the skin. If this is true, then the relationship is:

$$F = C \frac{dP}{dt} + \frac{1}{R_{(V)} + R_{(P)}} P \quad (17)$$

where $R_{(V)}$ equals resistance controlled by vaso-motor tone, and $R_{(P)}$ equals resistance controlled by intraluminal pressure P . At present, the coefficients C , $R_{(V)}$ and $R_{(P)}$ are obtained only by measuring the flow and pressure without any means of indirect evaluation. Figure 20 illustrates one example of how C and R of equation 16 were adjusted until the dynamic flow pulse was computed from P (30). In this case flow was already known from simultaneous

measurement with the square-wave electromagnetic flowmeter.

There are apparently no positive reflections from the normal renal bed, hence the flow computed for the total renal circuit according to equation 16 and without an inertance term represents the flow in the renal artery. To compute, however, the instantaneous flow in other arteries from whose bed there are reflections one must use the difference in pressure along the artery (i.e., two pressure sources in the artery itself) and the equations 9 and 12. The most important term is then the inertial one of equation 9 although, as explained earlier, a further step in precise computation brings in the compliance of equation 12.

Carotid Artery Flow

This is illustrated in figure 18. Like the renal flow there is a large constant flow component upon which there is superimposed a dynamic component. It is related to the carotid pressure by equation 16 with the conductance term $1/R$ being the largest by far.

Because the carotid and renal flow patterns are governed largely by the resistance, they are called viscous or resistance flow patterns. The resting flow patterns of the entire aorta, iliac, femorals, and subclavian arteries are called reactance flow patterns because inertance and compliance are dominant. They have a small constant flow when compared to their dynamic component and this frequently demonstrates a period of negative flow in early diastole.

Coronary Blood Flow

Coronary blood flow in the unopened artery was first measured by Marston and Spencer with the square-wave electromagnetic flowmeter (24). The resting patterns differ little from those of Gregg (18) who used a cannulating system and orifice meter. The equation relating coronary flow to the vascular pressures is a modification of equation 16:

$$F = C \frac{dP}{dt} + \frac{1}{R} \Delta P \quad (18)$$

where ΔP equals the aortic pressure minus the ventricular pressure minus the right atrial pressure. Figures 21 and 22 (27) illustrate the measured left anterior descending coronary flow and the circumflex coronary artery flow.

These coronary inflow curves display a marked dependence on both aortic pressure and intra-

FIG. 20. Computed renal blood flow. P = the abdominal aorta pressure at the level of the renal artery. dP/dt = the first derivative of the abdominal arterial pressure. F_c = computed blood flow using equation 16. The lower tracing is measured blood flow using the square-wave electromagnetic flow-meter on the renal artery.

ventricular pressure where coronary resistance is a complex function of vasomotor tone, intra-arterial pressure, and intramuscular pressure. The function of intramuscular pressure which reduces inflow during systole increases venous outflow during systole and may also increase capillary flow at the same time.

IV. FLOW IN THE SYSTEMIC VEINS

Phasic variations in venous blood flow result from three principle sources: 1) the beat of the heart; 2) the respiratory fluctuations; and 3) the contraction of skeletal muscle. Severe changes in position and acceleration of the body also may have profound effects on venous flow. Pulsatile flow originating from the heart beat may occur in the small peripheral veins, as a result of transmitted oscillations from the arterial system. These pulsations are generally small in the normal condition because of the damping action of the resistance of the small arteries and arterioles and the elasticity of the capillary bed. They may be accentuated, however, by vasodilatation, either by reactive hyperemia or by means of drugs, such as acetylcholine. Flow in the renal vein, normally phasic presumably because of the low renal vascular resistance, causes less damping than in most vascular beds. Great variations in blood flow within the thoracic vena cava have been recorded by Brecher (5) and others.

Effect of the Heart's Action on Vena Caval Flow

It has been shown by Gauer and Sicker [quoted in (5)] that there is an almost immeasurable gradient

in the mean blood pressure along the venae cava toward the heart. Since there is a net movement of blood in that direction, some small gradient must be present which may be sufficient, in view of the large size of the channels, to move considerable blood. It is also true, according to the principles of vascular hydraulics discussed in sections II and III, this chapter, that considerable blood may be moved by an oscillatory pressure gradient without consideration of a mean frictional gradient (fig. 23).

Atrial contraction injects a late diastolic quota of blood through the tricuspid valve and also causes a pressure transient to pass along the vena cava away from the heart. This pressure transient produces a sharp reduction in flow which may or may not cause a reversal depending upon its amplitude and the level of mean flow (fig. 24). This impediment or reversal is, however, overcome immediately by a large forward flow caused by ventricular contraction. This "vis a fronte" which draws blood toward the heart during ventricular systole arises from movement of the base of the heart (tricuspid valve closed) toward its apex, producing a transient pressure gradient in favor of flow toward the heart. Flow may be expected to follow this differential pressure transient, approximately 90 degrees out of phase.

As the base of the heart moves away from the apex during diastole, the tricuspid ring dilates and filling of the heart takes place as much by the ventricle sliding over the atrial blood as by the atrial blood flowing into the ventricle. From direct observations of the heart and from slow motion movies, it can be seen that the ventricle fills by a) dilation of the tri-

FIG. 21. Coronary blood flow in the left anterior descending branch. The upper tracing represents the electrocardiogram taken simultaneously with the left ventricular pressure, aortic arch pressure, and coronary flow. [From Schenk (43).]

cuspid ring, *b*) engulfing of the atrial blood by the right ventricle, and *c*) a final quota of blood delivered by atrial contraction. The question of whether or not the ventricle produces a sucking force during diastole is unresolved. The answer will await definitive differential pressure measurements made across the ventricular wall.

Effect of Normal Respiration on Vena Caval Flow

This is illustrated in figure 25 (28). Inspiration greatly increases the venous return as shown in the thoracic vena cava and abdominal vena cava caudal to the renal veins.

V. PULMONARY FLOW

Right Ventricular Ejection Pulse

The form of the right ventricular ejection pulse (fig. 26) differs from that of the left ventricle in

FIG. 22. Coronary blood flow in the circumflex branch. Tracings taken from the same animal as in fig. 21. [From Schenk (43).]

general by an over-all lack of the higher frequency components. The initial acceleration is slower, peak more rounded, at a somewhat lower velocity; and the reverse flow due to pulmonary valve closure forms a more rounded notch followed by a lower frequency aftervibration. There are also fewer random frequency vibrations throughout diastole. Presumably these differences arise from a slower rate of contraction of the right ventricle versus that of the left, and a greater compliance per unit of arterial wall in the pulmonary artery than that of the aorta, the latter arising perhaps from the lower distending pressure. When flow recordings are taken off the pulmonary trunk near the bifurcation, one frequently notices a low-frequency vibration during the diastolic period which may be due to some reflections from the pulmonary periphery.

Measurements of differential pressure across the pulmonary valve between the right ventricle and pulmonary artery display less of a tendency for the

FIG. 25. The effect of natural breathing on flow in the thoracic and abdominal vena cava of the dog (closed chest). Tracings represent from above downward. *AO* = the aortic pressure in mm Hg; *IT* = intrathoracic pressure in mm H₂O; *VC-1* = thoracic inferior vena caval blood flow in ml/sec; *VC-2* = flow in IVC below renal veins in ml/sec; *RA* = right atrial pressure in mm H₂O; *FV* = femoral vein pressure in mm H₂O; and *IA* = intra-abdominal pressure in mm H₂O. [After Mixer (28).]

FIG. 26. Left and right ventricular ejection pulses in congenital atrial septal defect before and after repair (7-year-old boy). Repair consisted of an open-heart procedure using total cardiopulmonary bypass while closing the defect by means of a suture technique. Figures between the flow pulse tracings represent the mean output of the ventricles averaged over several heart cycles. The contour of the tracings is typical of normal tracings found in humans and dogs. Stroke volume differs markedly, however, between the two ventricles before and after repair. The repair diminished pulmonary flow and increased the aortic flow. Presumably the difference between the pulmonary and aortic flow after repair results from either 1) incomplete closure, or 2) actual difference in the cardiac output between the measurements which were not taken simultaneously.

to an internal diameter of 3 mm. Blood flow throughout these degrees of experimental coarctation was maintained at the normal level and the stroke flow was maintained primarily by flattening the peak flow

and broadening of the systolic area. During this time a systolic murmur began softly and increased in loudness and duration; its envelope maintained a contour similar to the contour of the peak of the flow

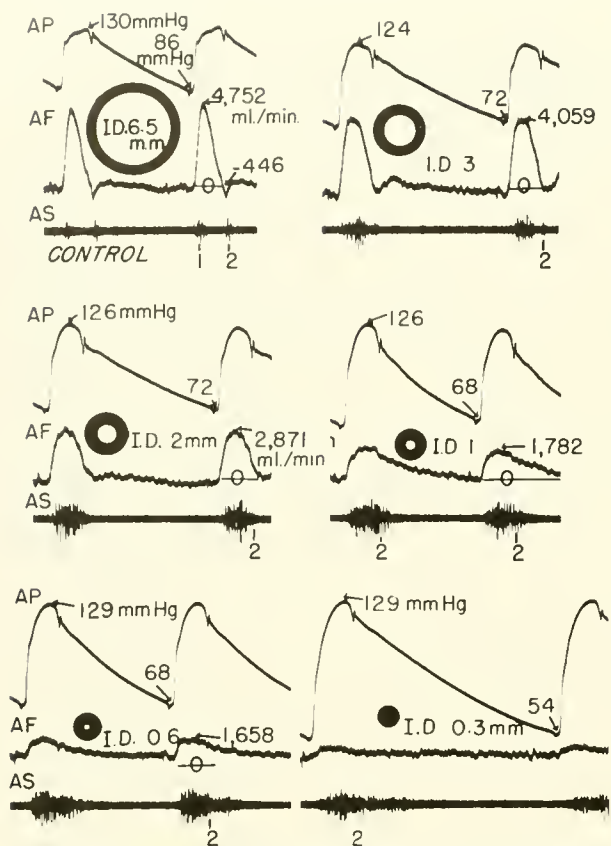

FIG. 27. Experimental graded coarctation of the descending thoracic aorta. *ID* = internal diameter; *AP* = aortic pressure; *AF* = aortic flow in the descending thoracic; and *AS* = aortic sounds. The sounds are taken by means of a barium titanate phonocatheter downstream to the point of constriction. During control, systolic pressure was 130 mm Hg, diastolic 86 mm Hg. The peak systolic flow was 4,752 ml/min, while the mean flow in the descending thoracic aorta was 446 ml/min. In spite of the reduced peak flow, there was little reduction of mean during the early stages of constriction because of change of contour of the flow pulse. The pressure gradient, flow pulse contour and murmur envelope follow the "contour rule."

pulse. Presumably, this remarkable reduction in cross-sectional area without reduction in flow is attributable to the progressively increasing gradient across the stenotic area.

Beyond this degree of obstruction any further change in the internal diameter becomes extremely critical as far as blood flow is concerned. With an internal diameter of approximately 2 to 3 mm, the murmur consistently filled systole throughout, and further reduction caused the murmur to increase in duration beyond the second sound and extend into the diastolic period. Internal diameters of 1 mm or less frequently caused a continuous, high-pitched, blow-

ing murmur distal to the site of coarctation in both experimental animals as well as in congenital lesions.

The Murmur Envelope and Contour Rule

The "envelope" of a murmur is defined as the amplitude of the full wave rectified murmur averaged over several heart cycles. The term envelope is similar to the "shape" of a murmur which itself means amplitude of the unrectified murmur. The envelope of a blowing murmur follows a "contour rule," which means that it corresponds closely to the contour of the flow pulse originating the murmur. This is true because apparently once the critical velocity is reached where turbulent flow begins (turbulence is used in a general sense to indicate nonlaminar flow), the amplitude of the resultant turbulence or lateral velocities of the nonlaminar flow is proportional to the mean axial velocity. Further, the flow under these conditions is principally viscous in nature and therefore the extant resistant pressure gradient contour parallels the flow pulse contour. The correspondence of the murmur envelope and the pressure gradient to the flow pulse exists only when the flow is highly viscous in nature (having no significant reactance flow term), and may occur without stenosis in a normal vessel under high-velocity conditions producing nonlaminar flow or in an aneurysm where nonlaminar flow may be achieved. Some examples of the contour rule are given in section VII.

General Rules Relating Murmurs to Nonlaminar Flow

From this and other studies in section VII, general rules concerning the interpretation of frequency band width and envelope (amplitude and duration) of "blowing" murmurs may be made relative to the functional anatomy of the source as follows:

1) Blowing murmurs with high pitch and low intensity are associated with small orifices through which blood is flowing at high velocity, driven by large pressure gradients.

2) Loud, blowing murmurs of relatively low-frequency spectrum, generally sounding coarse to the ear are associated with relatively large orifices through which large volumes of blood flow under relatively high-pressure gradients.

3) Very low-frequency (rumbling) murmurs of low intensity are associated with turbulent flow beyond large orifices through which blood flows under low-pressure gradients.

4) The contour of the time-intensity pattern or "envelope" of a murmur corresponds to the contour of the flow pulse passing through the region at the time of murmur production.

5) Musical murmurs, that is, murmurs with periodic reproductions in the frequency pattern as opposed to the random vibrations of blowing murmurs, arise from tissue structures, or other coherent material, set into oscillation by blood flow of high velocity.

Examples of general rule 1 are found in the continuous aortic murmur of severe degrees of coarctation and the diastolic murmur of minimum aortic regurgitation. Examples of general rule 2 are moderate degrees of coarctation, aortic and pulmonary valve stenosis, Korotkoff's sounds, patent ductus arteriosus, and the murmurs of most arteriovenous fistulae. Examples of general rule 3 are mitral stenosis, tricuspid stenosis, and occasional right atrial murmur of an interatrial septal defect. Examples of general rule 4 are really found among all murmurs wherever one compares the murmur envelope with the flow pattern as illustrated in section VII on flow in pathological conditions. Examples of general rule 5 are the vibrations of a vein wall giving rise to a "venous hum," the "sea gull" murmur arising from vibration of aortic valve cusps in aortic regurgitation, and the "moaning" systolic murmur of retroverted mitral cusps, or arising from vegetation on the mitral cusps giving rise to a systolic low-frequency periodic murmur in mitral regurgitation. In addition, musical qualities may be heard in arteriovenous fistulas which are presumably due to the vibration of the vascular wall, and are usually superimposed, like most musical murmurs, upon blowing or random noise vibrations.

VII. NORMAL AND PATHOLOGICAL FLOW PULSES IN HUMANS

The normal human flow pulses closely resemble in pattern those which have been found in the corresponding vessels of the dog and sheep. Most records of human flow pulses have been made at the time of a surgical procedure indicated because of some pathological condition. The pulses in this section presented as "normal" tracings are so called because there was no physiological reason to doubt their normalcy and second, because they correspond to those found in the experimental animal.

Flow in the Ascending Aorta

Normal blood-flow patterns are shown in figure 26. As in the dog, they show a rapid acceleration phase, a slower deceleration phase with a high-frequency (40–60 cps) backflow coincident with aortic valve closure. The volume of the flow pulse has little effect on these contour features (fig. 26) except from hypodynamic ventricles and severe degrees of exercise. Diastole is relatively uneventful with the resonant wave not appearing. The ejection pattern of the left ventricle in the presence of aortic valve stenosis is shown in figure 28. The principal deviations from normal contour seen here are a more flattened and delayed peak, with flow vibrations superimposed. In addition, there is less prominence of the valve closure backflow wave. The backflow wave incident

FIG. 28. Aortic valve stenosis of rheumatic origin without regurgitation in a 14-year-old boy. Measurements were made during thoracotomy prior to repair. Flow pulse shows the rounded irregular top of turbulent blood flow, corresponding to a diamond-shaped murmur and a pressure gradient between the left ventricle and ascending aorta which follows the contour rule

FIG. 29. Blood flow and pressure gradient in aortic valve regurgitation without stenosis in a 19-year-old girl. In ascending aorta flow, the zero reference is estimated. The regurgitant blood flow, the envelope of the diastolic murmur, and the pressure gradient between ascending aorta and left ventricle follow the contour rule. The blood flow pattern during systole is not greatly altered from that of the normal, in spite of increased stroke volume (see also atrial septal defect, fig. 26).

to valve closure is not, per se, dependent upon absence of aortic stenosis, but rather upon the degree of flexibility of the valve. If the valve is stiff and immobile, this wave will disappear. If the valve, as in congenital stenosis, is flexible, this wave will persist and also one may differentiate subaortic stenosis or outflow stenosis from valvular stenosis by the presence of a stenosis pattern during systole which retains the normal amplitude of the valve closure wave.

The severe pressure gradient across the stenotic valve, as shown by the difference in the aortic pressure and ventricular pressure when recorded directly, is

quite similar in contour to the flow-pulse contour (fig. 28). The murmur, which is harsh, loud and blowing, and is located in the ascending aorta and arch, has an envelope with a contour closely paralleling that of both the peak of the flow curve and differential pressure curve. Experimental aortic stenosis produced by means of a wire tightened about the ascending aorta at the sinus of Valsalva is shown in figure 5. The effect of varying degrees of stenosis is demonstrated on the flow curve, the aortic arch pressure, and the differential pressure between ventricle and ascending aorta. Also of note here is the heart's ability to maintain a stroke volume in the face of this severe increase in load impedance. Under the conditions of this experiment, in which several heartbeats were allowed for cardiac compensatory mechanisms to act, the left ventricle functions as a constant flow source. Further compensatory mechanisms brought into play over long periods of time, particularly allowing hypertrophy of the left ventricular wall, further enhance the heart's ability to maintain a constant stroke with a severe increase in load impedance.

Aortic regurgitation causes changes both in the systolic and diastolic contour of the left ventricular ejection pulse (fig. 29). The systolic stroke volume exceeds the normal volume by the amount necessary to compensate for regurgitation during diastole. As a result the flow pulse tends to be somewhat more rounded, but otherwise maintains the general shape of the normal pulse. However, because of the greater stroke volume, there is necessarily a greater acceleration and deceleration at the onset and termination of ejection. The valve closure notch disappears, and in its place one sees a sustained backflow deflection. The backflow, diminishing throughout diastole, is a function of the diastolic pressure gradient across the valve, and the size of the regurgitant orifice. The murmur, which has a wide frequency band extending above 100 cps, sounds high pitched and blowing, begins with reversal of the pressure gradient across the valve, usually builds up early in diastole to a maximum, and then follows a decrescendo proportional to the backflow. As seen from figure 29, the envelope of the diastolic murmur is similar to the pattern of the diastolic backflow.

Descending Thoracic Aorta

Figure 30 illustrates flow in the descending thoracic aorta immediately distal to a ductus arteriosus, before and after the closure of the ductus. The descending

FIG. 30. Flow in the descending thoracic aorta distal to a ductus arteriosus while patent and after the ductus was occluded. Simultaneous recording of the descending aorta pressure was made by means of a needle inserted near the square-wave electromagnetic probe.

thoracic flow following closure of this ductus may be taken as the shape of the normal flow in the human descending thoracic aorta. Variations in contour show basic similarities to those of the dog's descending thoracic aorta of section III. It is of interest to note that the mean forward flow in the descending thoracic aorta distal to a patent ductus arteriosus is not affected by closure of the ductus. This finding indicates what is confirmed by flow in the descending thoracic aorta proximal to the patent ductus, namely, that the left ventricle compensates for a ductus arteriosus by increasing its output just a sufficient amount to make up for the flow passing through this

FIG. 31. Blood flow through a patent ductus arteriosus. Contour of the flow pulse follows closely that of the contour of the aortic pressure thereby indicating strong predominance of resistant blood flow in this situation. The murmur was continuous and had an envelope the contour of which followed the contour rule. Pulmonary pressures were normal.

FIG. 32. Blood flow through a patent ductus arteriosus in a patient with pulmonary hypertension. There was a net flow of blood into the aorta. Flow from pulmonary artery into the aorta took place during systole, and from aorta into the pulmonary artery during diastole. The greater pulse pressure in the pulmonary artery as compared to that in the aorta undoubtedly resulted from the lower compliance of the pulmonary tree as compared to that of the systemic arterial tree. The three records: aortic pressure, pulmonary artery pressure, and patent ductus flow, were taken at different times in rapid succession.

shunt to the pulmonary artery. The flow through the ductus is predominantly viscous in type, as its contour follows closely that of the contour of the differential pressure between the aorta and pulmonary artery (fig. 31). The envelope of the murmur follows the contour rule of the differential pressure and flow pulse in a viscous flow situation. The murmur envelope and flow contour are closely represented

FIG. 33. Congenital coarctation. Tracings from above downward both before and after resection are: descending thoracic aorta pressure, blood flow through the coarctation area, low-frequency phonocardiogram, and high-frequency phonocardiogram. Blood flow records both before and after resection were made at the same sensitivity setting of the electromagnetic flowmeter. Zero reference after resection was not obtainable because of danger of rupture of the suture line. On the basis that zero was somewhat lower than the lowest flow point, the mean flow was estimated to be greater than 1800 ml/min after resection, while the mean flow before resection was 475 ml/min. Some constriction remained after resection and suture.

FIG. 34. Tricuspid regurgitation after the differential pressure method of Müller & Shillingford (29). Blood flow is recorded between the superior vena cava and the right atrium in a normal subject in record A, and in a patient with tricuspid incompetence and high venous pressure in record B.

by the contour of the aortic pressure pulse alone, because normally it greatly exceeds the pulmonary artery pressure at all times throughout the cardiac cycle. Because of this situation, the murmur is continuous throughout the cardiac cycle.

Figure 32 illustrates a flow pulse through a ductus of an unusual type. In this situation, chronic pulmonary hypertension had developed until the pulmo-

nary pressure exceeded that in the aorta during systole, and was less than that in the aorta during diastole. (The larger pulse pressure in the pulmonary tree than in the systemic arteries probably resulted from the smaller compliance of the pulmonary tree.) As a result, ductus flow was from pulmonary artery to aorta during systole, and from aorta to pulmonary artery during diastole.

Coarctation of the aorta also produces a viscous type flow through the stenotic region (43, 49). Most patients with coarctation have a severe degree of the type illustrated in figure 33. The differential pressure and murmur envelope both follow the contour rule with reference to the flow pulse. Flow pulses in the aortic branches are considerably altered (43).

Tricuspid Valve

Blood flow between the superior vena cava and the right atrium was measured by a pitometer by Müller & Shillingford (29). This record probably represents a close approximation of the flow pulse at the tricuspid valve except for the period of atrial contraction which is inverted to show forward flow (fig. 34).

- Vessels of the Muscular Type
- Capillaries and Arteriovenous Anastomoses
- Veins

Nutrition of the Vascular Wall

- Diffusion from the Inside
- Vasa Vasorum

BLOOD VESSELS serve as a conducting system for the blood. They carry the blood, forced by the heart, throughout the whole body and back again to the heart. To make this possible there must be a pressure gradient with its highest values in the aorta and its lowest values in the large veins. The circulation therefore withstands a much higher pressure on the arterial side than on the venous side, a difference which is reflected in the architecture of the wall.

The stress on the vessel wall is, according to Frank (30), proportional to the blood pressure and the ratio of radius to wall thickness

$$\sigma = \frac{p \cdot r}{t} \quad (1)$$

[\(\sigma\) = stress (force per unit area), \(p\) = pressure, \(r\) = radius, \(t\) = wall thickness].

The relationship \(r/t\) and the composition of the vessel wall (fig. 1) show the level of blood pressure. For example, the aorta has a much smaller ratio of

\(r/t\) than the vena cava, which means that the difference between the wall tensions of the two vessels is less than might be expected, considering the difference between the blood pressures to which they are subjected [Burton (20)]. The relationship \(r/t\) is smaller in vessels where the principal component is smooth muscle than in vessels where the major component is elastic tissue. For that reason, the smooth muscles, the contractile elements of the wall, need to withstand smaller stress than the elastic tissue, one of the passive elements of the wall.

The vessels must be tight, so that no blood is lost on the way through the circulatory system. The vessel wall is therefore lined with the endothelium, which serves as a semipermeable membrane for the exchange of material between blood and tissue.

The arterial side of the circulatory system is not only a simple conducting system, but is also an elastic buffering chamber. The vessels, mainly the aorta, are stretched during systole, and store energy which enables them to force the blood along by elastic recoil during diastole. This ability is given the vessels by their elastic tissue. However, as Frank (31) has shown, tubing which consists only of distensible material like rubber will “blow out” at a critical pressure. This does not occur in normal blood vessels, since they have a relatively inextensible jacket in addition to the elastic tissue. This jacket is composed of collagen tissue, and is located in all arteries and veins. The collagen tissue bears the stress when the pressure becomes high, protecting the vessel from rupture or blow out.

Another quality of blood vessels is their ability to regulate the blood supply to different organs, depending on the need. When an organ is active, more blood must be carried to it than when it is at

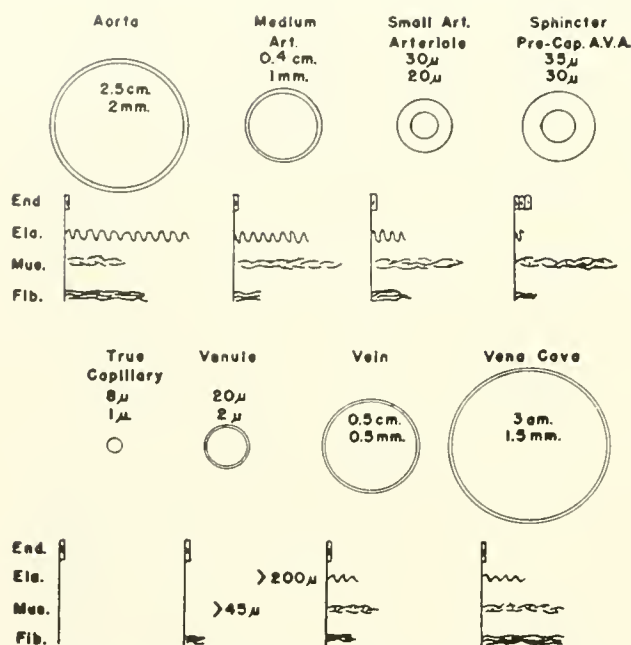

FIG. 1. Variety of admixture of the four tissues in the wall of different blood vessels. The figures under the name of the vessel are the diameter of the lumen and below it the thickness of the wall. [Burton (20).]

rest. This is best done, according to the law of Poiseuille, by changing the radius of the small supplying vessel by relaxation of the smooth muscles in the arterial wall.

Any living organ must be nourished. All but the smallest blood vessels have their own circulatory system, the vasa vasorum, which supplies blood to the vessels from the outside. In addition, simple diffusion from the inside transports nutrients and oxygen to the inner avascular layer of the blood vessel. This outward fluid shift may be aided by the radial pressure gradient through the vessel wall.

The purpose of this chapter is to discuss and to interpret these qualities and functions of the vascular wall and to explain the performance of the various wall elements in the different types of vessels.

ELEMENTS OF THE VASCULAR WALL

The terms used in this article are, for the most part, those defined by Landowne & Stacy (50). Here we will consider some of these terms in detail. Collagen tissue, elastic tissue, and smooth muscle have three qualities in common, which appear differently. These qualities are elasticity, visco-elasticity, and plasticity.

Elasticity is that property of a material which

determines its tendency, when stressed, to return to its unstressed geometrical configuration without loss of energy. If a material is completely elastic, all energy applied to it by an external straining force can be recovered as mechanical energy. Figure 2a shows an extension release cycle of such a perfectly elastic material, illustrated by a spring. Any given length has its particular tension. The extension curve and release curve are the same. It can be linear, as in figure 2a, or convex or concave to the abscissa, depending on the material stretched. Tension-length diagrams of organic materials usually show a curve which is convex to the abscissa. A perfectly elastic

FIG. 2. Behavior with stretch of different materials. Tension and length are taken as arbitrary. *a*: Elastic material, demonstrated by a spring. Extension and release curve are the same. *b*: Visco-elastic material demonstrated by a spring, which has a brake disc on the top and which moves in a liquid. Extension and release curves inscribe a hysteresis loop, the size of which depends on the velocity of the extension and release. *Outer curve*: fast stretch; *inner curve*: slow stretch. An infinitely slow stretch gives the same curve as *a*. *c*: Viscous or plastic material demonstrated with a brake disc, which moves in a liquid. The material keeps every length to which it was brought by an external force. The force depends on the velocity of the extension. *Upper curve*: fast stretch; *lower curve*: slow stretch. In each the rate of viscous deformation is constant.

material can maintain a constant tension at any given length for an indefinite time.

Thus, the term visco-elasticity applies to materials having the combined properties of elasticity and viscosity, the elastic action being damped by a viscous one. Such a system is most easily illustrated by a spring which has a brake disc at the top and moves in a viscous fluid. The tension of such a system depends not only on the length but also on the velocity with which it is extended. The tension will be higher the faster it is stretched, and also lower, the faster the stretch is released. When the extension-release cycle of such a system is plotted with tension on the ordinate and length on the abscissa, the graph forms what is called a "hysteresis loop." Two such cycles are shown in figure 2*b*. The large loop results from a quick stretch cycle, with immediate release, the small loop from a slow stretch cycle. The area between the extension curve and the abscissa is always larger than the area below the release curve. This behavior indicates loss of energy increasing with the velocity of the stretch. More energy is required to stretch such a visco-elastic material than can be recovered during release. The area within the hysteresis loop can be expressed as percentage of the area under the extension curve. It depends only on the velocity with which the system is stretched. Rapid cyclic stretches are called "dynamic stretches," and the shape of the extension-release curves depends on the frequency of the cycles. The hysteresis loop of a pure visco-elastic element will be larger in area, the more frequent the cycles. The hysteresis should vanish if the stretch is made slowly enough, and this is called "static stretch." If the stretched material is purely visco-elastic, it returns, after an extension-release cycle, to its original length. But if it is kept at a constant stretched length, the tension will decrease with time in a hyperbolic manner until it reaches an equilibrium. This process is similar to that shown in the two curves in figure 5.

A material is called plastic when it shows the tendency to retain its new shape after deformation. Plasticity is usually understood as the quality of a material which allows it to withstand stresses of less than a critical or yield magnitude without suffering a permanent set, but which will then allow a viscous deformation with stress above this yield value. The appearance of plastic yield is not time-dependent.

Viscous or plastic behavior is illustrated in figure 2*c* by a disk which is moved in a viscous fluid. The force required depends upon the velocity with which the disc is moved. The top curve in figure 2*c* is derived by a quick movement of the disc, the bottom curve by

a slow movement. As long as the velocity remains constant, the stress will be constant too. If the applied force is removed, the stress decreases without reducing the length. In contrast to the behavior of a visco-elastic element, a viscous or plastic element will never go back to its original shape by itself.

The systems shown in figure 2*a*, *b*, and *c* are very much simplified models to describe the physical definitions of elastic, visco-elastic, and plastic properties. These properties reflect, in organic materials, their complicated molecular structure. In organic materials there is usually a combination of the three qualities described, with elastic, visco-elastic, and plastic properties behaving as though arranged in series, and present in different amount. Such a combination is described by the term "elastic incompleteness."

For instance, if an elastic and a visco-elastic element are in series, then the element which offers the smaller resistance to extension will dominate the stretch behavior. Since the resistance of the visco-elastic element is greater at high rates of stretch, the properties of this series combination is determined more by the elastic element. The more frequent are the stretch cycles, the less is the hysteresis. If there is also a purely viscous or a plastic element in series, after every stretch cycle the material assumes a greater length. There is also the possibility that many visco-elastic and viscous elements may be in series, each having a different rate- and time-dependency. Such combinations of elastic, visco-elastic, and plastic elements can show a very slight rate-dependency, if, for instance, the elastic element offers the smallest resistance to stretch when compared with the other elements present. Because of the visco-elastic or plastic units, the system may show a great time-dependency, which occurs as an elastic aftereffect or a relaxation when the material is kept on a constant stress or length.

The viscosity of organic materials may not only derive from a viscous flow within the tissue, but also from an architectural rearrangement involving the uncoiling or slippage of twisted elements. Such processes may be involved in the phenomenon of the "stable loop" seen in elastic arteries after a number of stretches, which does not show any rate or time-dependency but does depend on the existing tension level [Remington (73); see also Chapter 24]. The so-called viscosity or plasticity of organic materials may be complicated, and thus not follow the physical definitions. Further, there is usually a certain polarity to these tissues in that tension-length relations are different in various directions. Most organic materials

cannot be extended ad infinitum, but tear at a certain length.

Smooth muscle is a special case. It can be elongated like a purely plastic material and can behave at any given length like an elastic or visco-elastic material. But it can also recover its original length by contraction. This means that the plastic property of smooth muscle can be neutralized or hindered, leaving only the elastic or visco-elastic elements under stress, as a result of the action of the contractile element. [For further details see Reichel (71).]

Endothelium

The circulatory system is lined almost completely by a single layer of very thin polygonal-shaped cells, the endothelium. This forms a tight, smooth surface on the inside of the vascular wall and serves as a semipermeable membrane for the interchange of materials between blood and tissues. It has a high distensibility. Its ability for regeneration is very good. For instance, 3 weeks after implantation aortic grafts show a smooth continuous lining of endothelial cells, which presumably are built from fibrocytes [Petry & Heberer (67)]. A detailed discussion of the qualities of the endothelium is given in Chapter 29.

Collagen Tissue

Collagen tissue is produced by fibroblasts, which are located in all connective tissues. The probable precursors of collagen fibers are the reticular fibers. These are argyrophilic fibers which are found especially in places where collagen fibers are forming, as around aortic grafts. They both show a banded appearance under the electron microscope [see Wassermann (95)]. The collagen fibers consist of a network of long protein chains which are linked by H bonds and ionic bonds. This network is filled with an amorphous substance (mucopolysaccharide). Smaller fibers are glued together to larger fibers by a cement substance which is continuous with the ground substance.

This structure gives the collagen fibers a very high elastic modulus and also makes them very flexible [see Harkness (36)]. Collagen fibers are nearly 25 times as strong as elastic tissue but 15 times less extensible (table 1). Collagen fibers are found in all vessels, spread over the whole wall. They appear in the unstretched vessel wall as wavy bundles, but some of them become straightened if the pressure within the vessel is raised above the mean blood pressure [Reuterwall (74)]. This anatomical design, together with the

TABLE 1. *Elastic, Visco-Elastic and Plastic Behavior of Collagen and Elastic Tissue (102)*

| | Maximal Tensile Strength, kg/cm ² | Maximal Extension, in % | Irreversible Elongation in % of Total Elongation | Hysteresis in % of Area Under Stretch Curve |
|------------------------------------|----------------------------------------------|-------------------------|--------------------------------------------------|---------------------------------------------|
| Collagen tissue (tendon) | 660 (250-750) | 10 (5-12) | 67 | 57 |
| Elastic tissue (ligamentum nuchae) | 25 (12-45) | 150 (120-220) | 19 | 60 |

high elastic modulus, enables them to form a "jacket" [Burton (20)], which is put in action only when the fibers are straightened, by increased intraluminal pressure. Thus the collagen fibers are not strained by the normal blood pressure; they serve as a safety factor for the vessels and keep them from "blowing out" at high pressure.

Only the collagen fibers increase in number with aging, replacing frayed elastic fibers and degenerated smooth muscle cells [Meyer (58), Kobayashi (46)]. Since the elastic and muscular tissues originally supported the wall tension at normal blood pressures, the replacing collagen fibers must take over this task [Bader & Kapal (7)] with the result that the wall becomes less distensible. This is compensated until the sixth decade of life by enlargement of the diameters of the vessels involved [Simon & Meyer (86)]. However, collagen tissue, when overloaded, does show elastic incompleteness, which means that it is to some extent a plastic material (table 1). The fibers do not return to their original length immediately after extension and the residual elongation can be 67 per cent of the total elongation. This plasticity may produce a large hysteresis. It may be that such plastic property can account for the increase in vessel volume seen in aging.

Ground Substance

The ground substance has the properties of a colloid—it is water-insoluble, but can bind water. It consists of the mucopolysaccharides: hyaluronic acid and chondroitin sulfate. It is likely that chondroitin sulfate forms the cement substance which binds collagen fibers together, and hyaluronic acid serves as a lubricating material [see Harkness (36)]. Such a lubricating substance is necessary in the vessel wall, since the fibrous elements of the wall (collagen fibers,

elastic fibers, and smooth muscles) must be able to slide past each other with minimal friction during the pulsatile expansion of the vessel. The ground substance is a very viscous material and it probably contributes to the typical visco-elastic behavior of distensible vessels.

Elastic Tissue

Elastic tissue is a rubberlike material with high extensibility. It contains the protein elastin without any detectable amount of carbohydrate [Lansing (52)]. In contrast to collagen tissue, it is an extremely insoluble material, and is not influenced by boiling or autoclaving. X-ray diffraction and electron microscopy do not ordinarily show any internal organization in elastic fibers. It is therefore assumed that the protein fibrils lie without orientation within the fibers [see Lansing (52)]. This disorder gives the elastic tissue its high extensibility. It can be extended to twice its original length, but its tensile strength is 1_{20} to 1_{30} that of collagen tissue (table 1). This explains why it must be protected from excessive elongation and tearing in the vascular wall by the much stronger collagen fibers.

Elastic tissue forms fenestrated membranes which lie one over the other in elastic vessels. These membranes serve as footholds for the tension muscles (fig. 3). There is less elastic tissue in the more peripheral muscular vessels. It is only a very minor component in the arterioles and precapillary sphincters (fig. 1). Elastic fibers appear in the veins, increasing in amount as they near the heart. They are partly straight and partly wavy in unstretched vessels. The wavy ones become straight before the collagen fibers straighten out as the pressure rises [Reuterwall (74)]. At ordinary pressures the elastic tissue supports most of the tension in elastic vessels, whereas this task is performed by smooth muscles in the muscular vessels.

Elastic tissues usually fray with age. This is a normal change which appears in all vessels of old people. Calcification of the fibers is also progressive with age. In addition, the fibers undergo fragmentation, which finally leaves little more than dispersed granular material [see Lansing (52)]. Calcification is especially great in arteriosclerosis. However, Lansing (52) has shown that the percentage of elastin in the vessel wall does not decrease with age, while the calcium content rises in the human aorta from 0.4 per cent in the second decade to 7 per cent in the eighth decade. Frayed and fragmented elastic fibers remaining cannot support the wall tension at normal pressures. This

FIG. 3. Axillary artery (human). Irradiation of tension muscles in the elastica externa—*a*: in situ; *b*: elastica externa artificially lifted off. Muscle endings fasten on the elastic membrane. [Benninghoff (10).]

task is taken over in old age by collagen fibers, which are under stress with ordinary blood pressure [Bader & Kapal (7)]. Thus, the distensibility of the vessels decreases, but the volume of the aorta increases and its total elastic uptake may remain within normal limits so long as the increase in volume keeps pace with the decrease in distensibility [Kapal & Bader (44), Simon & Meyer (86)].

Smooth Muscle

The smooth muscle cell is an elongated spindle with a single elongated nucleus in the thickest part of the cell. The cells vary very much in size. In the vascular wall they are between 20 and 50 μ in length, with their greatest diameter between 5 and 10 μ . There are two types of smooth muscles in the vascular wall: "Spannmuskeln" (tension muscles), which are described in detail by Benninghoff (10, 11), and ring muscles.

The tension muscles are connected to elastic fibers and membranes, using them as tendons (fig. 3). They can thus raise the tension on the elastic tissue in the vessel wall by contraction (fig. 7) and so affect the blood pressure (see Arteries of the Elastic Type,

below). The smooth muscles of the aorta and the pulmonalis are almost exclusively tension muscles. But the proportion of tension muscles diminishes toward the periphery. The smallest arteries and arterioles have almost no tension muscles. They may appear again on the venous side of the circulatory system, but not in as large numbers as in the elastic arteries [Grau (34)].

The ring muscles are connected with each other. How they are related to the elastic and collagen tissue is not certain, but it is very likely that they have slack connections with both tissues. Since smooth muscles are almost completely surrounded by reticular fibers, it is possible that these fibers bind them together. The ring muscles form the greatest part of the wall in the muscular vessels, where they form a helical arrangement [Fischer (23), Schultze-Jena (84)]. Arterioles and precapillary sphincters consist mostly of ring muscles.

Smooth muscles have the general quality of spontaneous activity and self-conduction [see Bülbiring (17)]. Bozler (16) has concluded from this behavior that they form a syncytium, which would mean that the individual muscle cells are interconnected by protoplasmic bridges. But in reality they form a network in which every muscle fibril is surrounded by its own membrane, so that there are double membranes at places where the cells are in contact with each other [see Prosser (68)]. This network acts like a functional "syncytium," since an excitation can be conducted over the double membranes. This double membrane has a high resistance, and therefore the conduction in smooth muscles is much slower than that in nerve fibers. The conduction can be propagated over the whole organ, as in the uterus or the ureter (single-unit smooth muscles), or it can be limited to a certain area, as in the intestine [Bozler (16), Greven (35), Bülbiring (17)]. The limitation results from the presence of a higher resistance of the double membranes at certain places. The resistance can be changed so that the area which responds to a stimulus can be increased or decreased. Another characteristic of the syncytium is its response to stretch [Bülbiring (17)]. If smooth muscles of the intestine are stretched, the membrane depolarizes and spikes are produced (fig. 4). Contraction occurs and tension rises in direct proportion to the increase in spike frequency. But in addition to having independent conductivity and excitability, smooth muscles also receive innervation from both the sympathetic and parasympathetic nerve system. There are ganglion cells around the adventitia [Leontowitsch (55)] and nerve fibers in the media [Boeke (15)] of the

FIG. 4. Graph showing correlation between membrane potentials, spike frequency, and tension during spontaneous pendular rhythm recorded for 10 min. [Bülbiring (17).]

blood vessels [see also Staubesand (87)]. The autonomic nervous system can change the spontaneous activity of the smooth muscles by changing their membrane potentials.

In addition to the syncytium-like smooth muscles, there are also multiple-unit smooth muscles which are neither self-conducting nor spontaneously active. They receive extensive innervation and appear to be organized in some type of motor-unit plan [see Prosser (68)].

Little work has been done on the problem of the excitation and conduction of vascular smooth muscle. Therefore it is hard to say whether it represents a multiple-unit system or a syncytium. Monnier (62) has shown that the conduction of excitation in the mesenteric artery of cattle (an artery of the muscular type) is very slow (only about 2 mm/sec). This is much slower than the conduction of any known nerve, and in a range similar to other syncytium-like smooth muscles [see Bülbiring (17)]. The mesenteric artery also responds to stretch with a contraction. It may be assumed therefore that the muscles in the peripheral arteries behave as a syncytium. This is likely, in view of the relationship of blood pressure to flow. For instance, Thureau & Kramer (91) have shown that the flow in the kidney becomes constant if the pressure is raised above 90 mm Hg. This special flow-pressure relationship is due to an increase of resistance, effected by contraction of the smooth muscles in the preglomerular arteries. Similar behavior in the arteries of

the extremities is reported by Folkow (26). This idea has a long history, beginning with the contribution of Bayliss (9) in 1902.

It may be assumed that the contraction of smooth muscle is caused by the increase of tension in the vascular wall as a result of the rising blood pressure. There is no adaptation to the tension stimulus, which agrees with the results of Bülbbring (17) on the intestinal smooth muscle. Folkow (28) suggests that the tonus of the resistance vessels is maintained by myogenic activity of their smooth muscles, which are excited by the tension of the wall (similar to the case for intestinal smooth muscles shown in fig. 4). However, this autoactivity, in both types of smooth muscle, is controlled by the autonomic nervous system. Since the smooth muscles in the peripheral arteries are mostly ring muscles, it may be that the ring muscles can behave like a syncytium. The tension muscles are always interrupted by elastic fibers, and Prosser *et al.* (69) have found a much larger intercellular distance between the individual muscle cells in vessels of the elastic type than in other organs (1000 nm in the pig carotid artery as against 120 nm in the cat intestine). It is therefore very likely that they form a multiunit system in which the muscle cells receive extensive sympathetic and parasympathetic innervation. This impression is confirmed by Burnstock & Prosser (18), who got no response to stretch from the carotid artery, a vessel of the elastic type, or from the renal vein.

Over and over the idea appears in the literature that arteries may contract and relax as quickly as the heart and so force the blood to the periphery just as the intestine propels a bolus to the colon. One of its newer proponents, Dickinson (22), shows a contraction curve of a sheep's hepatic artery which develops its peak tension in about 3 sec after an unphysiological stimulus of 120 v. The slowness of contraction and the long latency speak against the possibility of the propulsion of blood by arterial contraction. This latter attitude is shared by Fleisch (25) and Wetterer & Kapal (99).

If smooth muscles are extended slowly they behave like a plastic material. They can maintain a given length, either short or long, for protracted periods with very low metabolism. However, this length maintenance does depend upon repeated stimulations of constant magnitude. If the stimulation is increased, these muscles respond by contracting, regardless of their initial length (except, of course, if already maximally contracted). From this it follows that there must be some mechanism which enables smooth muscle to shift its behavior from plastic when "set" in length to

visco-elastic, when contracting. Üxküll (93) has postulated for this a "Sperrung" (catch mechanism), signifying that the protein filaments within the muscle fibers "catch" at a certain length so that they cannot slip apart when tension is applied.

Three possible explanations have been offered for this behavior. The first, suggested by Reichel, is that the smooth muscle consists of two elements in series, an elastic element and a contractile element, where the contractile element can behave with either plasticity or contractility (70). If this is true, the "catch mechanism" could be described as a transformation of plasticity to contractility, where the element is "caught" at any length and thus is able to keep a given tension with a low metabolism or to contract. An alternative to this theory, suggested by Lowy & Hanson (56a), is called the sliding filament mechanism. They assume that thin discontinuous actin-containing filaments move relative to thick discontinuous paramyosin-containing filaments, as in striated muscles. Linkages are presumably formed during contraction between both filaments all of one type, with one rate of formation. The rate of breaking can vary from slow (tonic contraction, visco-elastic) to fast (phasic contraction, plastic) depending on the concentration of a relaxant present (i.e., 5-hydroxytryptamine). Repeated excitatory stimulation could maintain these linkages, whereas stimulation of inhibitory nerves could increase the rate at which they break [Lowy & Millman (57)]. A second possibility is that the plastic and the contractile elements are in parallel, with an elastic element in series. In such an arrangement the catch mechanism could be in the plastic element, whereas the contractile element could cancel any plastic deformation by contraction. Such a parallel arrangement is postulated by Johnson (41a). He assumes that the contractile system is formed by the actomyosin, and that paramyosin is situated parallel to it as the plastic element. Laszt (54) assumes a similar mechanism in the vascular smooth muscle. A third possibility is that the plastic and contractile elements are in series. In such an arrangement the contractile element could work only if the catch mechanism were put in action. But it would then be necessary to have a special mechanism to cancel the plastic deformation, such as the presence of both fast and slow contractile elements within the smooth muscle, the slow elements being virtually "plastic."

Whether any of these three mechanisms may be the real one is not clear. It is possible, too, that one smooth muscle may work by one mechanism and

FIG. 5 Average stress-relaxation curves of carotid and umbilical arteries. Vertical coordinate is given in percentage of total pressure rise, following injection. *Upper curve*, common carotid artery of the dog. *Lower curve*, umbilical artery of the human. [Zatzman *et al.* (103).]

others by another, since, for example, the uterus and the bladder are very different in properties and action [Bader (3)].

If a smooth muscle is stretched quickly to a certain length, it will show a tension increase. If this length is held for a longer time, the tension will decrease, at first quickly, later more slowly. This typical stress relaxation is a result of the visco-elasticity of the smooth muscle, which may be due to breaking of the linkages within the myofilaments. A typical stress-relaxation curve of smooth muscles is like that of the lower curve of figure 5. For further details of the mechanical properties of muscles, see Reichel (71).

If these mechanical properties of smooth muscles are to be compared with those of the vascular wall, one must keep in mind the modifying effects of collagen and elastic tissue [Remington (73)]. Another point is that most of the experiments with smooth muscles are made on organs other than blood vessels, *in vitro*, and without innervation. Smooth muscles *in vivo* are under a continuous stimulation, and they are also under constant contraction and tension in the vascular wall. It is therefore very likely that the smooth muscles of the vessel wall *in vivo* would show different visco-elastic and plastic behavior from those found during *in vitro* experiments.

Zatzman *et al.* (103) have shown that there is a great difference in the stress-relaxation behavior of the elastic carotid artery and the muscular umbilical artery. After 10 sec of stress, relaxation of the carotid artery amounts to about 20 per cent of the original tension, whereas in the umbilical artery it is about 95 per cent (fig. 5). This indicates that in the umbilical artery the tension is applied mostly to smooth muscle with its large visco-elasticity and plasticity. It is not easy to say to what degree smooth muscle is respon-

sible for the relaxation of the carotid artery, since elastic and collagen tissues may each have both a visco-elastic component (hysteresis loop during stretch cycle) and a plastic component [irreversible elongation (table 1)]. This passive behavior is responsible in part for the stress relaxation of elastic arteries [see Kapal (42)].

Smooth muscle tissue degenerates and decreases in amount with age, and is replaced by collagen fibers [Meyer (58), Kobayashi (46)]. This tends to render the arterial tree more rigid and to explain the systolic hypertension of old age. The high systolic pressure in this condition puts an extra burden on the heart. [See Bader & Kapal (5) and the paragraphs on elastic arteries below.]

Smooth muscles have the ability to regenerate. For example, Petry & Heberer (67) have described cell formations which are found on the inside of aortic grafts some weeks after implantation. These cells seem to be muscle cells, and are assumed to originate from fibroblasts.

DIFFERENT TYPES OF VESSELS

Vessels differ in their architectural structure and their behavior according to their varied tasks. There are, in general, four different vessel types: on the arterial side are elastic arteries and muscular arteries, but it is hard to say where the one ends and the other begins, since the structural changes are gradual. Usually the aorta, the pulmonary artery, the common carotid artery, the subclavian artery, and the common iliac artery are regarded as elastic arteries. Arteries more peripheral than the above, down to the arterioles, are classed as muscular arteries. After these are the capillaries, which consist mostly of endothe-

lium. Then there are veins, which are built to some extent like the arteries. The most striking difference between them is their mounting, for most arteries have a slack connection with the surrounding tissues, whereas the veins are more intimately bound up with the surrounding tissues to make a functional system.

Arteries of the Elastic Type

The wall of the elastic arteries is characterized by a high percentage of elastic tissue (fig. 1), which may be 40 per cent of the wall in the thoracic aorta, but decreases toward the periphery. The elastic tissue is mostly present as fenestrated membranes—up to 50 membranes located one upon the other. There are also star-shaped membranes in the wall of the pulmonary artery [Meyer (59)]. There is a network of elastic fibers between all these membranes. The membranes are connected by smooth muscles, the tension muscles, described by Benninghoff (10, 11). These tension muscles use the elastic membranes as footholds (fig. 3). There are no ring muscles in the thoracic aorta, but they appear in increasing numbers in the more peripheral arteries. Where the ring muscles exceed the tension muscles in amount the arteries are called muscular arteries. The collagen fibers are distributed over the entire wall. They lie there in wavy bundles, which become straight if the blood pressure rises over the normal mean value [Reuterwall (74)].

The large amount of elastic tissue and looseness of the collagen fibers give elastic arteries high distensibility. For instance, the aorta can be distended to a threefold increase in contained volume over that at

zero pressure. This high distensibility enables an elastic vessel to act as would an air chamber (Windkessel). The aorta contributes over 50 per cent to the total vascular air chamber action [Wetterer (98)]. If an elastic artery is stretched, it shows a typical S-shaped pressure-volume diagram, like that in figure 6 where “static” stretch curves are given for the thoracic aorta of a pig. [See Chapters 7 and 24 for the explanation of the typical S-shaped pressure-volume diagram of elastic arteries and its relation to the tension-length diagram. [See also Frank (30, 31).] A similar S-shaped curve may be obtained from a rubber tube within a nylon tube, where the nylon tube serves as a “jacket” [Bader & Kapal (6)]. In such a pressure-volume diagram the rubber tube is responsible for the curve below the inflexion point and which appears concave to the abscissa; the nylon jacket for the convex part above the inflexion point. This fact, together with the finding of Reuterwall (74) that when elastic tissue becomes straight collagen tissue is still wavy (i.e., still relatively unstretched) and the study of Roach & Burton (75) which involved differential digestion of collagen and elastic fibers of the iliac artery, indicates that the part of the pressure-volume diagram from zero pressure to the inflexion point reflects the extension of elastic tissue, whereas the part above the inflexion point is due to the collagen tissue [see Bader & Kapal (7)].

The upper curve of figure 6 is derived from a stretch curve made shortly after death, after the aorta was stimulated with epinephrine; the lower curve was made 8 days later when the smooth muscles were dead. Schöenberger & Müller (83) got similar results on cow aortas with dynamic stretches. Millahn & Jaster (61) stretched pig and cow aortas after relaxing the smooth muscles with acetylcholine, finding that the stretch curve lay below the curve given by the stimulated vessel. The pressure-volume diagram can shift to higher or lower pressures depending on the contractile state of the smooth muscle, but the shape of the curve never changes. This proves that smooth muscles can increase the wall tension without changing the elastic properties of the vessel, a finding which Benninghoff (10, 11) had proposed as a result of his microscopic studies. Bader & Kapal (5) concluded from their experiments that smooth muscle can be arranged neither in series with the elastic elements nor in parallel. Both arrangements would give, with stimulation, not only a shift of the stretch curve to higher pressures, but also a change of the shape of the curve.

Since the tension muscles are attached to the elastic

membranes, and the contraction of the smooth muscles seems to influence only the part of the curve which is ascribed to the extension of elastic tissue, Kapal & Bader (43) have designed a model which is similar to an arrangement which Burton (20) had published in 1953 in his highly stimulating review article. It shows the action of the tension muscles in elastic arteries.

In figure 7*a* the smooth muscles are relaxed; in 7*b*, they are contracted. The smooth muscles fasten

on the elastic fibers or membranes at right angles to the direction in which the elastic fibers are stretched. These fibers become elongated by contraction of the smooth muscles, but the circumference of the vessel is not changed (fig. 7*b*). The consequence is a rise in the tension of the elastic fibers. Since the model will be involved in a stretch in the direction of the elastic fibers, the tension muscles do not need to develop tension as great as the total wall tension, but can increase the stress on the elastic tissue with relatively little work.

This model has an advantage to neurophysiologists as well as to muscle physiologists. Heymans & Delaunois (37) have shown that the blood pressure decreases if the smooth muscles of the carotid sinus are stimulated by noradrenalin. Heymans *et al.* (38) obtained the same results by elongating the carotid sinus. They concluded from these experiments that the pressoreceptors located in the carotid sinus, which cause a decrease of the mean blood pressure after stimulation, do not respond to the blood pressure, but rather to the wall tension [see Heymans & van den Heuvel-Heymans (39)]. It is very likely that the pressoreceptors situated in the aorta work in the same way.

The pressoreceptors appear as a very fine network of neurofibrils (fig. 7*A*). They are mainly located in the adventitia of the carotid sinus [Sunder-Plassmann (89)] and in the adventitia and the outer part of the media of the aortic arch [Seto (85)]. Stöhr (88) has the impression that this network of neurofibrils shown in figure 7*A* may be only a part of the whole neurofibril mass of which the pressoreceptor is constituted. He assumes that smaller fibrils exist but are not visible because of limitations in the staining method and in the optical properties of the light microscope.

There are very few clues as to how the network of the pressoreceptor is related to the surrounding tissue. Sunder-Plassmann (89) has shown that the media of the carotid sinus is thinner than that of the nearby vessel, but the membrana elastica externa is thickened. The elastica externa in the carotid sinus shows a sharp boundary separating it from the media, but a more gradual merging with the adventitia. In this diffuse zone, which shows collagen fibers and large elastic membranes, the pressoreceptors of the carotid sinus are located, and the neurofibril networks show a certain degree of adaptation to the shape of the connective tissue. Ábrahám (1) describes the neurofibril networks of the aortic arch as nestling flat against the vessel wall. Their position follows the direction of the fibrous elements.

It may very likely be that in both the carotid sinus and the aortic arch, the neurofibril networks of the pressoreceptors are in one way or another attached to the connective tissue, especially the elastic membranes or fibers. Thus the pressoreceptors are assumed to be parallel to the elastic membranes or fibers, an assumption which agrees with the facts now available. They will be stimulated if the smooth muscles increase the tension of the elastic tissue by contraction. But now the stimulated pressoreceptors reflexly lower the blood pressure until the tension of the elastic fibers, and with them that of the pressoreceptors, decreases again to the normal value (equation 1). The tension muscles are thus able to change the blood pressure, as shown in the work of Bader & Kapal (5). The model of Kapal & Bader (43), and the results of Heymans *et al.* (37-39) agree very well. It also fits very well with the idea that the tension muscles are multiple-unit muscles, since they are a type of control organ which does not depend on the wall tension.

The model may also explain the higher resistance and blood pressure of older people in contrast to younger people. Smooth muscles degenerate with age and are replaced by collagen fibers [Meyer (58), Kobayashi (46)]. This means that the smooth muscles are no longer able to stretch the elastic tissue as much as in younger individuals. But if the tension of the elastic tissue is lowered by lack of smooth muscle function, the blood pressure will rise until the tension reaches a physiological value for the pressoreceptors. As the muscles continue to degenerate, the pressure needed to stimulate the receptors continues to rise, and this may be one of the various mechanisms which cause essential hypertension. Such a hypertension must be called "essential," since the weakness of the tension muscles cannot be diagnosed and there may be no clearly diagnostic anatomical change of the arterial wall. The only evident sign of such muscle weakness would be the hypertension.

However, in the aging process degeneration of smooth muscles, fraying of elastic tissue, and increase of the collagen tissue are accompanied by a decrease in the distensibility of the arteries. A 20-year-old aorta can be distended to 300 per cent of its zero-pressure volume, but a 90-year-old aorta can be distended only about 25 per cent [Simon & Meyer (86)]. If the inflexion point of the volume pressure is high and the curve reaches its slope of maximum distensibility at about 100 mm Hg (the normal mean blood pressure) (cf the 13-year-old aorta in fig. 8a), the work required of the heart is reduced in maintaining a physiological pressure level. If the inflexion

occurs at a lower pressure level, as after an increase of collagen tissue (older aortas), the mean blood pressure falls on a steeper slope of the pressure-volume curve. Under this condition the heart would have to work more were this disadvantage not compensated by enlarging the volume of the aorta. Figure 8a shows a fivefold increase in the volume at 100 mm Hg between the 13-year-old and the 85-year-old aorta. The volume change of the elastic chamber with each heart beat, that is, the volume which can be injected to give the physiological pulse pressure amplitude, remains nearly constant until about the sixth decade of life, as a result of the initial volume increase. This means that the heart work need not increase with the decrease of the wall distensibility [Simon & Meyer (86)]. The aortas over 60 years do not show any inflexion point; they are convex to the abscissa from the very beginning. This signifies that collagen tissue is already stressed near zero pressure. The pulmonary artery shows similar behavior, but the inflexion point occurs at a lower pressure, just as the pulmonary pressure is lower [Meyer & Simon (60), Frasher & Sobin (32)].

The ratio of radius to wall thickness, which is important in the relationship of the wall stress to the blood pressure (equation 1), is the same at zero pressure in aortas of different ages [Hieronymi

FIG. 8. *a*: Pressure-volume diagrams of the thoracic aorta of the human at different ages. *b*: The relationship of radius to wall thickness of the same aortas in relation to the pressure. [Bader (4).]

FIG. 9. Schematic presentation of the behavior of the different tissues in the wall of elastic-type vessels at different degrees of extension. Description in the text. [Bader & Kapal (7).] The stretch is in the vertical direction. The S-shaped line is the pressure-volume curve of a young human aorta.

(40)], but at 100 mm Hg this ratio is age-dependent (fig. 8*b*). It increases from the first decade of life until the end of the third decade and decreases from then until the end of life. The shift of this ratio, like the shift of the inflexion point, is caused by the increase of the collagen tissue. The arteries become more and more rigid with age. A rise of the blood pressure in older people does not change the tension on the elastica, and thus prevents stimulation of the pressoreceptors. This indicates that the regulation of the blood pressure of old people would become more and more unstable [Bader (4)]. Since the decrease of the ratio of radius to wall thickness in the aging aorta simultaneously decreases the wall tension (equation 1), the tension of the pressoreceptors must also become lower and lower. But this process may result in an increase of the mean blood pressure to get the pressoreceptor again on the normal tension level. A similar change has already been mentioned with the degeneration of the tension muscles. But since the changes in smooth muscles, and in the ratio of radius to wall thickness, with aging, are greater in proportion than the usual increase of the mean blood pressure, one may assume also a change in receptor sensitivity.

The interaction of the three wall elements in the elastic arteries, elastic tissue, collagen tissue, and smooth muscle, may be illustrated by the scheme of figure 9. Sections 1 through 4 represent different stretch phases. The stretch takes place in vertical direction. Both halves of each phase must be regarded together. The element *a* represents two elastic fibers which are connected by smooth muscles as in figure 7. Both elastic fibers are already straight at zero pres-

sure. The element *b* is an elastic fiber which is still wavy (unstressed). Both *a* and *b*, in the upper and the lower half, are under minimal stress. Element *c* is a collagen fiber. In the upper half it is less wavy than in the lower half. Phase 2 will be reached after the stress has begun. Element *a* is already stressed, whereas element *b* is just straightened. By this means the recruitment of the elastic fibers is represented. The stretch proceeds in phase 3, so that collagen fibers are partly straight and included in the stress (upper half). The collagen fiber in the lower half is still wavy. Elastic fibers only are stressed in phases 1 and 2, whereas elastic and collagen fibers are functional in series in phase 3. Now the length available for further stretching of the elastic fibers is only half as much as in phases 1 and 2, since a further stretch of the elastic fibers in the upper half is prevented by the collagen fibers. This means that the increase in extension, per unit rise in pressure, becomes less and the pressure volume diagram, which until now was concave to the abscissa, becomes convex. At last a point is reached where all collagen fibers are straight: phase 4. Elastic and collagen fibers are straight and parallel. Since collagen tissue is much less distensible than elastic tissue, the wall distensibility at this point depends only on collagen tissue. This model illustrates the wall architecture of a proximal elastic artery. The more peripheral the vessel, the more the ring muscles participate and the more the model of figure 9 will be combined with the model of figure 13 (see below).

The effect of changes with age in the arterial wall can be illustrated by having the stretch start in phase 2, 3, or 4. Thus unextensible elements are put in action at lower pressures than in young arteries

FIG. 10. Extension-release curves of the thoracic aorta of the human at different ages and with different numbers of stretches. I: 14 years old—(a) 4th stretch cycle; (b) 100th stretch cycle. II: 63 years old—(a) 3rd stretch cycle; (b) 15th stretch cycle. [Wagner & Kapal (94).]

[Bader & Kapal (7)]. The unextensible fibers might be collagen fibers or calcified elastic fibers which are under stress with small extension of the arterial wall [Roach & Burton (76)] or even with no extension at all.

Elastic vessels, like any tissue, show typical visco-elastic and plastic behavior. An extension-release cycle gives a hysteresis loop which depends in part on the velocity with which the stretch was applied [see Remington (72)]. There is also a shift, on repeated stretching, of the pressure-volume diagram toward greater volume at the initial pressure level, indicating some plasticity. Wagner & Kapal (94) have found with experiments on the human aorta that hysteresis is not only dependent on the stretch velocity, but also on the age of the vessel (fig. 10). It becomes smaller, the older the vessel is. The same effect appears if an aorta is stretched repeatedly. The more frequently the artery is stretched, the smaller is the hysteresis. The hysteresis is greater above the inflexion point of the pressure-volume curve than below [Wagner & Kapal (94)].

In large elastic vessels, contraction of smooth muscles does not influence the hysteresis [Remington (72)]. Kapal (42) has shown that the aorta responds to dynamic stresses as would collagen and elastic tissue, but not like smooth muscle. Therefore, it seems that the visco-elastic and plastic behavior of elastic arteries depends mostly on elastic tissue, collagen tissue, and ground substance, but only to a small degree on smooth muscles. This is confirmed by the

curves of figures 6 and the model in figure 7, where smooth muscles do not affect the mechanical properties of the vessel (see also fig. 5). However, in the more peripheral vessels the increasingly plentiful ring muscles have a correspondingly greater effect on visco-elastic behavior [see Peterson *et al.* (66), Bergel (12, 13)]. The greater elastic incompleteness of collagen fibers, as compared to elastic fibers (see table 1), agrees very well with the larger hysteresis in the upper, collagen-dependent part of the pressure-volume diagram. But with both collagen and elastic tissue, the elastic incompleteness seems to diminish as more stretch cycles are made. The similarity between decrease of the hysteresis with age and with repeated cycles has led to the assumption that, as a result of their elastic incompleteness, the vessels are distended more and more by the pulse pressure during their life, until they reach a stable state, eliminating the visco-elastic and plastic elements [Wagner & Kapal (94)].

Vessels of the Muscular Type

The more peripherally the arteries are located, the higher is the percentage of smooth muscles in the wall (fig. 1). In elastic arteries one cannot distinguish easily between intima, media, and adventitia, whereas in muscular arteries there is a clear separation of these layers. The media consists mostly of smooth muscles, the ring muscles. Between them are collagen and elastic fibers. The elastic membranes, typical for the

FIG. 10A: Longitudinal muscles in the intima of the branches of the bronchial artery. Schematic presentation of their different arrangements. [Weibel (97).]

elastic vessels, are concentrated in the elastica interna, which separates the intima from the media, and in the elastica externa, which separates the media from the adventitia. Attached to these membranes are the tension muscles, but they account for but a small percentage of the total vascular smooth muscles [Benninghoff (10, 11)]. The ring muscles are arranged in the wall in a helical structure [Schultze-Jena (84), Fischer (23)].

Arteries which are frequently extended in the longitudinal direction, like the branches of the bronchial artery of the lung, possess longitudinal muscles in addition to the ring muscles [Weibel (96)]. These longitudinal muscles are situated in the split membrana elastica interna and can be arranged either in fairly thick one-sided bundles, or as concentric shells which surround the whole lumen (fig. 10A).

The mechanical behavior changes in the same way as the anatomical picture, smooth muscle forming the major support of muscular arterics, elastic tissue of elastic arteries. In contrast to the elastic vessels, the muscular arteries can change their radius over a wide range. The smallest vessels, like the arterioles and the precapillary sphincters, can even close their lumens completely. Figure 11 shows pressure-dia-

FIG. 11: Pressure-diameter diagrams of a small branch of the mesenteric artery of the horse—*a*: 1st stretch cycle; *b*: 2nd stretch cycle; *c*: 6th stretch cycle. [After Wezler & Schlüter (100).]

FIG. 12: Pressure-volume diagrams of the vessels of the hand: an in vivo experiment. *a*: Temperature in the plethysmograph: 25.5 C (vessels contracted); *b*: temperature 31.5 C (vessels normal); *c*: temperature 36.0 C (vessels relaxed). [After Thron *et al.* (90).]

ter diagrams of a small branch of the mesenteric artery of the horse [Wezler & Schlüter (100)]. Six extension-release curves are made successively, the first, second, and sixth being shown. During the first stretch cycle the smooth muscles are assumed to be contracted, during the following cycles they are more and more relaxed. The first extension-release curve shows a large hysteresis, where the extension curve is concave to the abscissa and the release curve is convex. This indicates a very large visco-elasticity of the vessel wall, and very different behavior from that of elastic-type vessels for which the extension and the release curves have a similar shape. Later extension-release cycles show smaller hysteresis, and the exten-

FIG. 13. Schematic presentation of the behavior of the different tissues in the wall of muscular vessels with different degrees of extension. Description in the text. [After Wezler & Schlüter (100).]

sion curves also become convex to the abscissa. Schlüter & Wezler (80) have described other curves where the first extension curve had an S-shape or was convex to the abscissa. In all these cases the shape of the diagram seems to depend very much on the state of contraction of the smooth muscles. The extension diagram will be concave to the abscissa if the smooth muscles are contracted, and the slope of the curve will be steeper the stronger the contraction. If the smooth muscles are less contracted, the extension curve will show an S-shape or be concave to the abscissa. The whole diagram moves with frequent stretches to larger diameters or volumes, but comes back to the original place if the smooth muscles are stimulated. Thron *et al.* (90) obtained similar results *in vivo*. Figure 12 shows plethysmographically obtained pressure-volume diagrams of the human hand vessels at different states of contraction of the vascular muscles, due to different temperatures. The extension curve of the constricted vessels (*a*) is nearly straight and is followed during release by a large hysteresis. The less constricted vessels have less hysteresis with both distention and release convex to the abscissa. This agrees very well with the diagrams of Wezler & Schlüter (100), which were made *in vitro* (fig. 11).

The diagrams shown in figures 11 and 12 are in many ways different from the diagrams in figures 6, 8, and 10, which were made from the elastic aorta. The most striking differences are: first, the shape of the aortic diagram remains the same whether the smooth muscles are contracted or relaxed; second, the hysteresis of the elastic vessels is smaller than that of the muscular vessels. This indicates that the arrangement of the different wall elements must differ in the two types of vessels. The smooth muscles, which play only a minor role in the elastic vessels, take a major one in the stretch curve of muscular vessels. Wezler & Schlüter (100) have designed a model which may give the action of the three wall elements and in

different contracted states. This model is shown (simplified) in figure 13. It is distinguished from the model in figure 9 by the parallel arrangement of the smooth muscles to the other elements. Sections 1 through 3 represent, as in figure 9, different stretch phases. The stretch takes place in the vertical direction. The element *a* represents an elastic fiber, the two elements *b* are smooth muscles, where the individual muscle fibers are in series, and element *c* is a collagen fiber. Both the elastic and the collagen fibers are wavy (unstressed) in phase 1. At the beginning of the stretch, near zero pressure, only the smooth muscles bear the stress. If the muscle fibers are contracted the slope of the pressure-volume diagram will be steep in the beginning and concave to the volume abscissa. Since the contracted smooth muscles behave in general like a visco-elastic material, the pressure-volume diagram will show prominent hysteresis as described in figure 2*b*. If the muscle fibers are relaxed, the slope of the pressure-volume diagram will be flatter. As extension proceeds, phase 2 will be reached, in which the elastic fibers are straightened. This will be at a higher pressure if the muscles are contracted than if they are relaxed. Finally, the collagen fibers are involved in the stretch (phase 3). If the smooth muscles are in strong contraction, the whole diagram within physiological pressure limits is concave to the volume abscissa. If the contraction is less, the elastic and collagen fibers come into play at lower pressures and the pressure-volume diagram shows an inflexion point and an S-shape. The pressure at which the inflexion point is located depends on the intensity of the contraction. If the smooth muscles are relaxed, the vessels will show in the beginning only a plastic elongation without a rise of pressure, but the pressure will increase when the elastic and collagen fibers are involved in the extension. The pressure-volume diagram is, from the very beginning, convex to the abscissa. The collagen fibers

serve as a "jacket" just as they do in the elastic vessels. They provide a safety factor to prevent overstretching the smooth muscles.

The model of figure 13 gives only the arrangement of the ring muscles in relation to the other elements. The more centrally the arteries of the muscular type are located, the greater is their amount of tension muscles [Benninghoff (10, 11)]. We must then assume a mixture of models shown in figures 9 and 13. The change over from the pure elastic-type model (fig. 9) to the pure muscular-type model (fig. 13) is gradual. The different behavior of the arteries may be the reason why different authors have different opinions about the architecture of the same wall. For instance Burton (20) suggests an arrangement similar to figure 9, whereas Bergel (12, 13) speaks of an arrangement similar to figure 13. Both may be right.

The smooth muscles in the muscular arteries are, during life, under a continuous stress since they are in parallel. Therefore they must have a certain basic tone to withstand the stress of the blood pressure. There is strong evidence that this basic tone may derive from myogenic activity. Bayliss (9) suggested, in 1902, that the blood pressure might act as a mechanical stimulus to the vascular wall. Lately it has become more and more evident that the smooth muscle possesses the capability of spontaneous activity (see above). For instance, denervated intestinal smooth muscles respond to a stretch with a contraction (fig. 4). The tonus of the vascular smooth muscles may be assumed to depend on the tension of the wall and consequently on the pressure within the vessel. Folkow (26), Thurau & Kramer (91), and earlier workers have found that the blood flow becomes constant above a certain pressure which may mean that the pressure or, rather, the wall tension serves as a stimulus for contraction of the smooth muscles, and so causes an increase in the peripheral resistance (see above). This autoregulation of flow results in a homeostasis of wall tension for, in contracting, the smooth muscles increase the thickness of the wall and reduce the radius of the lumen. Both of these changes reduce tension on individual muscle fibers. So the vascular smooth muscles may keep their tension near a constant level by contraction, when the pressure rises.

The suggestion has been made that basal tone may derive from locally released constrictor agents or regional reflex arcs of independent nerve plexuses in the vascular wall. However, Folkow & Öberg (29) have recently published experiments which eliminate these possible mechanisms. These experiments show

that the basic tone of precapillary resistance vessels and autoregulation of flow is not due to nerve plexuses or vasoconstrictor agents, but to myogenic activity. The task of the autonomic nervous system, which innervates the vascular muscles, would then be to control the myogenic activity and adjust it to the appropriate situation of the circulatory system (see above). In the same way tone may be controlled by chemical agents. This matter is also discussed in Chapter 37.

As the pressure perfusing a vascular bed is gradually reduced, the flow becomes less in proportion, the exact nature of this relation changing under different circumstances and with various vascular beds, as discussed in Chapter 28. The flow stops before the arteriovenous pressure difference reaches zero. The pressure at which this stoppage occurs has been called the "critical closing pressure" by Burton (19). The physical and physiological factors which determine the height of this pressure are discussed in Chapter 6.

Capillaries and Arteriovenous Anastomoses

The arterial side of the circulatory system is connected with the venous side by two types of vessels: capillaries and arteriovenous anastomoses (see also Chapter 27).

Capillaries are the tiny vessels through the walls of which materials are exchanged between blood and the tissues. They consist of a thin layer of endothelial cells, which sit on a basal membrane. On the outside of the capillaries are found the pericytes, which are cells with many irregular branches. Capillaries have no smooth muscles and, in spite of earlier contentions to the contrary, it is the current consensus that the pericytes cannot constrict mammalian capillaries (see Chapter 27); nor can the swelling of endothelial cells cause stoppage of flow [for additional references see Illig (41)].

The arteriovenous anastomoses are vessels the walls of which consist almost entirely of smooth muscle. They serve as a direct connection between the arteries and veins, bypassing the capillaries. The large amount of smooth muscle enables the arteriovenous anastomoses to keep their lumens closed over long periods of time. It is not impossible that these anastomoses regulate the capillary blood flow through the several organs, according to their activity. If an organ is active the anastomoses close and the blood may flow through the capillaries, whereas in a resting

[v. Kügelgen (48).]

organ, the anastomoses may open and let the blood bypass the capillaries.

Anastomoses in the lung possess longitudinal muscles. Weibel (96, 97) has demonstrated that these muscles always appear in those vessels which have to withstand longitudinal elongation. He assumes that the longitudinal muscles support this stretch.

Veins

The veins, in contrast to the arteries, are very variable in their wall structure. Usually they have a larger percentage of collagen fibers than the arteries, but there are veins in which the muscular mass exceeds by far that of the collagen fibers. Veins have little elastic tissue (fig. 1). The arrangement of the wall elements is both circular and longitudinal in varying proportions in different veins. Tension muscles seen attached to elastic fibers in arteries seldom appear in veins. Grau (34) described elastic-muscular systems in the large veins of the cow, similar to the tension muscles described by Benninghoff (10, 11). However, v. Kügelgen (47, 49) could never find such tension muscles in human veins. He described, rather, muscles like the arterial ring muscles, the individual muscle cells being connected together as a network. This network of smooth muscles is tied to the collagen fibers and the intima.

Figure 14 shows the percentages of smooth muscles and collagen and elastic fibers in different human veins. The smooth muscles are separately graphed as transverse (circular) and longitudinal muscles. The longitudinal muscles of the veins are not arranged in bundles in the intima, as are those of the arteries. Rather, they form a network in the wall with the circular muscles, the smooth muscles being either longitudinal or transverse, or at any other angle.

The circular muscles are mainly in the veins of the leg, whereas the longitudinal muscles predominate in the abdominal veins. Figure 15 shows that the proportion of circular muscles parallels the pressure in the veins in the erect posture, there then being considerable hydrostatic pressure in the human leg veins. Since the wall tension in a tube, in the transverse direction, is twice that in the longitudinal direction [Frank (30)], the percentages of circular muscles are higher in veins subject to higher pressures. Hydrostatic pressure and wall tension vary with posture; therefore this variable pressure load can be supported better by muscles capable of myogenic activity, as in arteries, than by collagen or elastic tissues (see above). Along with the higher amount of smooth muscles in the leg veins the relationship of radius to wall thickness is less than that of other veins [v. Kügelgen (48)]. Veins of the thorax,

FIG. 15. The relationship of the abundance of transverse (circular) muscles in human veins (smooth line) to the venous pressure in the erect posture (dotted line). The numbers indicate the same veins as in fig. 14. [v. Kügelgen (48).]

abdomen, and neck are not under this hydrostatic stress and have less circular muscle tissue.

The mechanical properties of the veins are similar to those of the arteries. Smaller veins show different pressure-volume diagrams, depending upon the state of contraction of their smooth muscles, as do those of muscular arteries [Alexander (2)]. The only difference between the diagrams of the muscular arteries and the veins is that the diagram of the veins is located at much lower pressures. This indicates that the elasticity of small veins depends to a high degree on smooth muscle. The large veins, like the vena cava, give a pressure-volume diagram more like that of elastic arteries [Blömer (14)]. It shows an S-shape, like the aorta, with an inflexion point at the low pressure of about 7 mm Hg. This S-shape does not depend on the activity of the smooth muscles. The main support of the wall tension of the large veins, at least above 7 mm Hg, is the collagen tissue rather than the elastic tissue, as is the case for elastic arteries, since the amount of collagen exceeds by far the amount of elastic tissue in the vein wall. The relatively high distensibility of the vena cava, in spite of the collagen fibers, may depend on a gradual recruitment of these fibers, as shown in figure 9, phases 3 and 4, or it may be due to a reorientation of the network formed by the collagen fibers in the venous wall [see v. Kügelgen (49)].

The most striking difference between arteries and veins are that the veins possess valves and are securely embedded in the surrounding tissue (33, 51, 53, 78),

whereas the arteries never have valves and they are loosely connected with the surrounding tissue.

The valves of the veins are folds of the intima. They consist of collagen and elastic fibers but not of smooth muscles. Around the vein at the base of the valve is a thickened band of collagen fiber (51). Usually two valves face each other [Bardeleben (8)]. The leg veins are best guarded by valves. Very small veins are said to be free of valves [Klotz (45)], as are the venae cavae. The valves minimize postural hydrostatic pressure changes in the leg veins, protecting the capillaries and the veins themselves from unphysiological pressures.

The action of the skeletal muscles, compressing, stretching, and releasing the veins, and even arterial pulsation (53, 78), cause periodic changes in venous capacity. Since the valves open toward the heart, these movements cause the veins to act as pumps, promoting return of blood to the heart and maintaining low capillary pressures (for further details see Chapter 32).

The numbers of valves in the veins depend very much on the age of the individual. Many valves degenerate with aging. Bardeleben (8) has ascertained, for example, that the greater saphenous vein of a child has, on the average, 13.6 valves, whereas that of an adult has only 10.7 valves. Klotz (45) has even found up to 70 per cent of atrophied valves at age 70. The first sign of degeneration is a functional insufficiency of the valves permitting leaking at higher pressures when the vein is distended, although they

still are tight at low pressures [Schlüter (79)]. Further degeneration makes them leaky at low pressures and later they are so degenerated that only a small margin remains or the valve leaflets are broken through. At last they vanish completely. The effects of venous valvular insufficiency are discussed in Chapter 36.

The firm anchorage of the proximal part of the veins may facilitate transmission of arterial pulsation from arteries to their venae comitantes [Schade (78), v. Lanz *et al.* (53)], but it seems also very convenient for another task. Any distensible tube which stands upright and is filled with fluid tends to pull downward. The radius in the proximal part is then small and the wall is stretched mainly in a longitudinal direction. It is therefore necessary that the tube be supported in the proximal part in the longitudinal direction and be fixed to its surroundings. Such a support may be formed in the veins by the bracing straps (33, 53) and also by the longitudinal muscles. In the distal part of such an upright tube the radius is enlarged and the wall is stretched mainly in a transverse direction. As indicated above, this is countered by the increasing amount of circular muscles.

NUTRITION OF THE VASCULAR WALL

The vascular wall is a living organ and its smooth muscles need a source of energy. Their nutrition is accomplished by two different means: diffusion from the circulating blood from the inside of the vessel toward the outside, and from the vasa vasorum vessels which dip into the vascular wall from the outside. These two supply routes meet in the vascular wall. Müller (64) has demonstrated a model in which ten coaxial thin rubber tubes with increasing diameters were telescoped and fixed so that the fluid between the different sheets could not escape during distention. This model satisfies very well the situation in the vascular wall, which is also built from different layers consisting of different materials. The pressure between the sheets is equal to the negative radial stress, and the tension of the different sheets of the model decreases nearly linearly from the inside to the outside at any given internal pressure. The innermost sheet has almost the same pressure as the filling fluid, whereas the outermost sheet is at the ambient pressure. This means that the vessels which supply the vascular wall meet progressively higher pressures the further they penetrate the wall. On the other

hand, the pressure gradient from the inside toward the outside facilitates the movement of materials directly from the circulating blood through the wall. The border between diffusion and vascular supply in the vascular wall depends on the thickness of the wall. The limit for diffusion is set by oxygen, which is transported in the blood by the hemoglobin and which can supply tissues adequately if the distance from the hemoglobin, which stays in the blood, to the tissue cells is not too great. This distance is, in the vascular wall, about 500 μ [Linzbach (56)]. The limit for the vasa vasorum is set by the pressure in the wall. Since the vasa vasorum come mostly from the adventitia, the pressure fall over the length of the vasa vasorum allows them only to penetrate as far as the pressure in the wall is less than the pressure of the intramural capillaries.

Diffusion from the Inside

The whole circulatory system is lined with a single layer of endothelium. This lining prevents extravasation of blood even if the pressure in the vessels exceeds by far the surrounding pressure. Any nutrient material entering the vascular wall from the inside must pass across this endothelial lining. Such penetration is rendered possible either through the pressure and concentration gradient between the blood and the wall tissue or by means of active transport. Chambers & Zweifach (21) assume that the individual endothelial cells are held together by a cement substance and that this cement substance makes penetration possible. However, Linzbach (56) could never find such a cement substance. He describes cell branches which are near the basal side of the endothelial cells, and with which the endothelial cells are very tightly connected. The boundary between the cells may form fissures, where capillary attraction may be effective and render penetration possible. Pappenheimer (65) suggests channels between the endothelial cells with a diameter of 30 to 45 A, through which the materials can enter the wall. All these mechanisms depend on a pressure gradient between the blood and the wall tissue or an osmotic concentration gradient of the different materials.

However, there may also be active transport. Moore & Ruska (63) described small vacuoles on the surface of the endothelial cells which contain blood plasma. These vacuoles separate themselves from the surface and wander through the cell sub-

FIG. 17. Schematic longitudinal section through the aortic wall at the origin of an intercostal artery. *I* = intercostal artery; *V* = vas vasis externum; *a* = outer branch; *i* = inner branch. [Schönenberger & Müller (82).]

stance to the basal side of the endothelial cells, where they release their contents to the wall tissue. This transport is called cytopempsis. Another possibility of active transport through the endothelium may be by a similar mechanism which was described by Ussing (92) for the frog skin. He demonstrated that sodium is actively transported across the skin cells by a carrier system located in the cell membrane. This would mean that ions or other materials enter the endothelial cell passively through the surface membrane, along a concentration gradient, and are then actively transported out of the cell and into the wall tissue against a concentration gradient. Sawyer & Valmont (77) have published evidence for such a mechanism in the canine thoracic aorta and vena cava, where the net flux of sodium or chloride ions

FIG. 18. Cross section through the thoracic aorta of the dog, showing a vas vasis internum. There is no branching of capillaries in the intima and the innermost part of the media. The dark masses in the outer third of the media are accumulations of injected material that has broken out of the capillaries. [Woerner (101).]

in the aorta is from the inside to the outside. In the vena cava it is in the opposite direction (for a possible explanation of this contrasting behavior see below). The variety of theories about the transport of material across the endothelial lining shows that much work remains to be done. Most of these theories are deduced from experimental results on capillary endothelial cells but it may be that transport differs in the capillary endothelium and the endothelium of larger vessels. There is also the possibility that different tissues use different transport mechanisms. (See also Chapter 29.)

The further transport through the intima and the media may be passive in the intercellular space,

[Lang (51).]

effected by the pressure and concentration gradient across the vascular wall.

Vasa Vasorum

The vasa vasorum penetrate the vessel wall to different depths, depending on the thickness of the wall and the type of vessel. The thicker the wall, the greater the part of the wall tissue they supply. In general, veins have greater vascularization than arteries. The vasa vasorum penetrate the aortic wall as far as the inner third of the media (fig. 16). The innermost part of the media and the intima are always free of capillaries. Only arteriosclerotic vessels with a thickened intima show vascularization of the innermost part of the wall [Woerner (101)].

The vasa vasorum of the aorta can be classified as vasa vasorum externa and vasa vasorum interna. The vasa vasorum externa originate near the origin

of arterial branches, such as the intercostal arteries. They soon divide into an outer branch and an inner branch (fig. 17). The outer branch goes into the adventitia and from there sends branches into the wall, whereas the inner branches remain within the wall. Their branching is mostly trichotomous. The vasa vasorum interna originate directly from the lumen (fig. 18) far away from branching vessels, that is, in the aorta on the ventral side [Schönenberger & Müller (82)]. They are not very numerous; according to Woerner (101), there are never more than two per square centimeter. They are mostly found in the proximal part of the aorta and very seldom in the distal part. The vasa vasorum externa and interna anastomose in the aortic wall. The vasa vasorum externa are about 65 to 70 mm in length, the vasa vasorum interna about 30 to 50 mm.

The more peripherally the arteries are located, the less vascularized is their wall. Figure 19 shows a schematic drawing of an artery with its two venae comitantes from a human shank. The vasa vasorum of the peripheral arteries arise at smaller branches of the artery, similar to the vasa vasorum externa of the aorta. There are no vasa vasorum interna in these arteries. The vasa vasorum never dip into the media. They are located in the stratum longitudinale fibroelasticum, the innermost part of the adventitia. They form their capillary loops mostly in the longitudinal direction. In addition to these capillary loops there are still smaller vessels. Lang (51) has described two types of such small vessels. The first type is a small, blind-ending channel about 3 mm in length and 1 to $3\ \mu$ diameter (fig. 19) which is much too small for blood cells to pass. These small channels run into the tip or the venous part of the capillary loop. The second type is a network of small channels of about the same diameter (fig. 20).

The same vas vasis which supplies the artery also supplies its venae comitantes (fig. 19). In contrast to the case for arteries, the capillaries in the venous wall form a dense network which extends to the media. The segment around the valves is usually not vascularized. The venous vasa vasorum do not drain directly into the large vein along which they lie; rather they and their counterparts in the arterial wall drain into a small venous branch [Lang (51)].

Schönenberger & Müller (82) have calculated the drop of pressure in the vasa vasorum externa of the aorta, finding that the capillary pressure within the wall can be sufficiently high only if the origin of the main vas vasis is very near the inner surface of the aortic wall (fig. 17). The intramural capillaries must be quite near to the origin of the vasa vasorum externa

FIG. 20. Net-shaped small channels with a diameter of $1-2\ \mu$ in the adventitia of the peroneal artery. Capillaries of the sheath and the arterial sheath partly removed. The small channels were connected with the capillaries of the sheath. *a*: Wall capillaries in the stratum longitudinale fibroelasticum; *b*: network of small channels; *c*: arterial sheath and capillaries of the sheath, in situ. [Lang (51).]

to maintain a pressure which is necessary to exceed the tissue pressure. If the capillaries are too far from the origin, the pressure will be too low to supply the wall efficiently. At greater distances from the intercostal arteries, the vasa vasorum interna, with their short delivery system, may provide sufficient blood supply.

Schönenberger & Müller (82) have also determined the flow and resistance in the vasa vasorum of the cow's aorta. Flow increases and resistance decreases, with rising pressure, with a maximum at

about 140 mm Hg (distended vessels). At higher pressures, a decrease of flow and an increase of resistance occurs (collapsed vessels). The maximal flow seems to occur at the systolic blood pressure level. This indicates that nutrition of the vascular wall may be problematic in hypertension, if the diastolic pressure exceeds the physiological systolic pressure, since the flow in the vasa vasorum may never reach the maximum. The inner region of the wall, which is not nourished by the vasa vasorum, also suffers ischemic changes, including a compensating increase in vascularity.

The lymphatics certainly play no role in the circulation of the tissue fluid within the vessel wall itself, as they do in other organs. The very small channels which arise from capillaries (see above) and which have a diameter of 1 to $3\ \mu$ may function like the lymphatics with local drainage (51). The mechanical or hydrostatic pressure gradients are irrelevant to this diffusion transport and determine only the direction of flow in the vasculature of the vessel wall—whether the supply to a capillary comes from an internal or an external arterial branch.

The situation in the veins is quite different from that in the arteries. There are no channels of supply from the lumen of the vein as is the case in the artery and, since the venous blood is depleted of oxygen and nutrients, the supply by diffusion through the intima is nonexistent or very limited. The pressure gradient is from the external arterial plexus to the capillary plexus, extending as far as the intima. Venous drainage is into small venae vasorum rather than into the lumen of the large vein. The interstitial space is probably drained by "lymphatics", although the fluid may pass directly across the intima and into the lumen. The pressure gradient is favorable for this movement of fluid and it might nourish the non-vascular inner wall. This concept agrees very well with the experiments of Sawyer & Valmont (77), who have found a net transport of Na and Cl from the outside to the inside in the canine vena cava.

Summary

ALTHOUGH CAPILLARY VESSELS in living animals have been observed microscopically for three hundred years, there is a great diversity of opinion regarding the structure and function of minute vessels in terminal vascular beds. Actually, a survey of the descriptions of patterns formed by capillary networks and the flow of blood through them in a wide variety of tissues and organs reveals great similarity in vascular patterns and also in the manner in which blood flows

from arterioles through capillary nets on to collecting venules. This similarity of structure and function leaves the impression that acceptable generalizations, applicable to these terminal beds, must be developed in order that future studies may prove profitable.

It is well known that unnecessary disagreement arises from lack of uniformity in terminology. It is equally obvious that unnecessary confusion arises from assigning complex functions to isolated components of a specific vascular bed when, in truth, both the activity and the structure are common features of small blood vessels anywhere.

DEFINITIONS

Any attempt to supply a list of universally acceptable definitions of vascular structures would be useless, and yet it is necessary to present some generalizations regarding current usage of terms before describing the types and variations of structural patterns that connect distributing arteries and collecting veins.

The term "microcirculation" is used to designate blood flow through small vessels at the capillary level (48). The microcirculatory bed is the ultimate portion of the cardiovascular system which is generally accepted as being concerned with the transfer of gases and nutrients and the removal of metabolic waste products. Minute precapillary arterioles and postcapillary venules are included with the capillaries as major components of the microcirculation (53).

Terminal arterioles are the final arterial ramifications, the branchings of which continue as non-muscular capillary vessels (88). They are further

defined (152) as vessels which have a single layer of smooth muscle and very little supporting connective tissue. The "metarteriole," a term introduced by Chambers & Zweifach (20), is defined by Zweifach (148) as a primary structural unit which serves as a framework for the distribution of capillaries.

The term "precapillary sphincter" was first used by Chambers & Zweifach (20) to designate the muscular investment at the origin of the outflowing branches of the preferential channel (distal continuations of arterial vessels that go directly to the venous side). These outflowing branches lead into true capillaries. In more general usage, a precapillary sphincter is the last smooth muscle cell along any branch of a terminal arteriole (130).

A capillary may most simply be described as an endothelial tube devoid of smooth muscle and having a minimal amount of supporting elements (48). In descriptions of vascular patterns and flow it is not necessary to add any qualifications as to size, direction of flow, or function.

Venules originate at the appearance of the first smooth muscle cell on a postcapillary vessel. Venules merge into veins which have a double coat of circular and longitudinal muscle cells.

Vasoconstriction is the contraction of the smooth muscle of the vessel wall, vasodilation is relaxation of the smooth muscle. Vasomotion refers to any active change in the diameter of blood vessels (81, 89).

There are numerous other designations for vascular structures, unique to specific organs or tissues, which will be discussed where they appear in the descriptions of arteriovenous pathways in various sites.

TECHNIQUES FOR MICROSCOPIC OBSERVATION OF SMALL BLOOD VESSELS

In discussing the techniques used for microscopic observation of small blood vessels, the most commonly used sites and methods have been included. There are numerous adaptations of the basic techniques for specific approaches, and also many highly specialized adaptations for specific areas that will be described in sections of this chapter where they are pertinent.

In general, there are four basic methods: 1) observation of tissues and organs *in situ* illuminated by the fused quartz rod, 2) exteriorization of internal tissues or organs which can be spread out as a thin layer for examination, 3) preparation of tissues using transparent chambers, 4) utilization of superficial structures which can be seen with direct or transmitted light.

The brevity of the descriptive material should not mislead the reader as to the difficulty of mastering the technical problems associated with each method, nor should he overlook the necessity of being completely familiar with the characteristics of the site selected for observation. A survey of the methods should make it clear that some sites or structures are more suitable than others for any specific investigation and should be evaluated on that basis.

Hamster Cheek Pouch

A method for observation of peripheral circulation at the microscopic level in the membranous cheek pouch of the hamster has been developed by Fulton, Jackson, and Lutz (51, 52, 80). The cheek pouch of the anesthetized hamster is everted and, when properly exposed for viewing, forms a flat double-layered preparation suitable for low power magnification. The pouch is bathed in a 37°C Ringer's solution. If higher magnifications (200× to 1200×) are used, it is necessary to cut through the upper layer to form a flap of a single layer. The originators of the method believe that the cheek pouch is ideally suited for investigations on small blood vessels because the thin membrane presents a normal physiological surface with blood vessels in their usual tissue environment. A valuable feature of the pouch is also that the same natural vascular bed can be studied over long periods and thus changes in circulation or other characteristics, such as growth of vessels, can be followed. The pouch is more vascular than the mesentery of rats or membranes in transparent chambers. Its vascularity makes tumor transplantation extremely successful. Other investigations made on the hamster cheek pouch include the study of blood pressure, inflammation, hemostasis, petechial formation, thromboembolism, bacterial and parasitic infections, drugs, and the vascularization of tumor transplants.

The disadvantages of the preparation are that the animal is anesthetized, the exposed tissue must be irrigated and kept at body temperature, and for high magnifications the integrity of the vascular bed is disrupted by surgery needed to obtain a single-layered membrane. The membranous surface continuously exudes mucus, which reduces visibility of the underlying structures. In the hands of its originators, judging by their excellent films, the method is very satisfactory for the investigations in which it has been used.

Transparent Chamber

The development of the transparent chamber technique and its utilization in numerous tissues have been extensively reviewed recently (3, 24, 25). For a detailed description of the methods for installation and observation, the reader may refer to these papers.

Basically, the method consists of the insertion of a glass and mica chamber fastened to the cartilage of the rabbit ear or other applicable site. Since the first chamber was designed by Sandison (104) in 1924, several types have evolved, with modifications and improvements introduced for specific purposes. The round-table chamber, essentially the same as the original Sandison model, was introduced in 1930 by Clark *et al.* (36). The chamber is constructed to allow new tissue to grow into an empty space from the edges of cartilage left by a punctured hole. This chamber has been used to study the growth and development of blood vessels, lymphatics, and nerves. The preformed tissue chamber (36) is one in which the original tissues can be observed after removal of the cartilage and skin of the inner side of the ear. The moat chamber was developed to study the response of the vessels to various chemical substances (1, 2). It contains a small space or moat to permit injection and withdrawal of fluids. The chamber has been used to investigate absorption, diffusion, and the reactions of vessels to chemical solutions. A removable-top chamber was designed by Williams (138) for the purpose of obtaining easy access to living tissue of the chamber for transplantation of organs or tissues. The most recent improvements have been developed by Williams & Roberts (140), who designed a versatile and highly useful chamber which has the following characteristics: it has a longer life than any other type of chamber, produces very little irritation to the ear, is quickly and easily installed, can be used for transplants of tissue, may be modified to study existing or preformed vessels, and may be adapted for the introduction or removal of fluids. Epidermis, which invades the round-table chamber, is never seen to grow into this new tantalum and mica chamber.

Clark (25) points out the many advantages of the transparent chambers, among them the fact that the manner of growth and extension of capillaries, the growth of nerves along arterioles, and the development of inflammatory reactions can be observed for long periods of time in unanesthetized animals. The disadvantages include injury to the nerves during installation, the rigidity of the chamber which may

result in an abnormally high external pressure, especially with inflammation, and the occurrence of infection. The advantage of having an unanesthetized animal is great, and equally helpful is the fact that the exposed tissues need not be warmed or irrigated as is the case for visceral or other exteriorized tissues. A serious disadvantage of the technique is the disruption of normal circulatory patterns and behavior by installation of the chamber in which the new tissue must form.

Fused Quartz Rod

A lengthy discussion of this method of transillumination of living internal organs in situ for microscopic study is given by Knisely (70). The limitations and the applications of the method are fully covered.

The method is based on conducting intense light to the structure to be studied by a fused quartz rod. These rods conduct light around bends and turns by internal reflection. Overheating and drying of the tissue is prevented by an isotonic wash solution. Magnifications from 20 times to 1000 times can be used.

Transillumination with the fused quartz rod has been carried out in a wide variety of tissues including frog skin, tongue, brain, gastrointestinal tract, stomach, bladder, striated muscle, lung, kidney, and liver. In mammals, the small vessels in smooth muscle, mesentery, uterus, spleen, and liver have been studied.

Knisely feels that the limitations of the method include the necessity for an anesthetic, surgery, and the exposure of internal organs to the air. The method is best used to examine structures at their natural anatomical surfaces or free edges rather than at cut surfaces. In examining a thick organ, such as liver or spleen, one is limited in the degree of magnification of the deeper structures due to the direct relationship between the focal length and magnifying power of lenses. Fulton (49) points out that this procedure does not reveal certain details of vascular structure or permit critical discernment of individually formed elements. It remains, however, the only method applicable to many types of tissues, but requires rational selection of the problems to be studied.

Bulbar Conjunctiva

Although observations of the conjunctival vessels are not new, recent improvements in microscopes and

lights have made this site a popular one, especially for observing changes in vascular patterns and flow in diseases in humans. Specific instructions for its use can be found in papers by Bloch (15), Grafflin & Corddry (56), and Lee (76).

The type of microscopic and lighting equipment, as well as the position of the patient (supine or upright), varies with the investigator, but, generally, compound microscopes, routine ophthalmological supports, and lights of moderate intensity constitute the basic components.

Bloch (13) notes that the walls of the blood vessels are not clearly seen because of the use of oblique illumination, although a moving column of blood can be clearly seen against the white background of the sclera. Other limitations are that optical resolution is lost by the patient's inability to hold the eye still, edema, highlights due to lacrimation, and excessive abnormal pigmentation in some cases. Very high magnification is difficult because of movements of the eyeball and the inability of the patient to tolerate light of high intensity. Also, high power objectives must be too close to the eyeball if they are to be in focus.

The advantages of the technique are that blood vessels in an unanesthetized human can be readily observed without any surgical intervention or any preparation to render the vascular beds visible. Tears supply the proper irrigation for this membranous tissue. An entire vascular field can be studied again and again in the same subject, and blood flow can be followed from arteriole through capillary to venule.

Rat Mesoappendix

The technique for microscopic observation of mesenteric structures, as described in detail by Zweifach (145), has been used by him in studies on dog omentum and mesenteric structures in several animals, but primarily in the cecal mesentery (mesocecum) of the rat.

Preparation of this tissue consists of exteriorizing the cecum of the anesthetized rat and then spreading the mesentery, which lies between the cecum and the terminal ileum, for observation. The mesentery is continuously irrigated with a warm Ringer's gelatin solution.

Zweifach (147) believes that the advantages of using this terminal vascular bed are: *a*) the accessibility of the vessels for direct stimulation by mechanical, chemical, or electrical means; *b*) clarity of visualiza-

tion; *c*) minimum interference by surgical procedures to normal vascular behavior; *d*) adequate display of the entire extent of the terminal vascular bed.

The disadvantages include those which apply to any technique using anesthetized animals subjected to surgical procedures to expose the tissue for observation. An idea of the lability of this vascular bed may be obtained by reading the precautions to be taken in using the rat mesoappendix for bioassay (153).

Bat Wing

Microscopic observations of vascular structures in the bat wing, a comparatively old technique (68), was revived by Nicoll & Webb (88) in 1946. A description of the preparation and current uses may be found in papers by Webb & Nicoll (130) and Wiedeman (136).

An unanesthetized animal is slipped into a holder that allows the wings, lightly held by spring clips, to be extended over a glass plate. Magnifications up to 2500 times can be used with good resolution.

The simplicity of the preparation is one of its great advantages, coupled with the elimination of anesthesia and surgery which permits observation without disturbing the normal circulation or subjecting the animal to undue stress. The blood vessels and lymphatics are accessible for cannulation which permits perfusion of drugs or measurements of pressure, and the nerves can be readily stimulated or sectioned. Also, in this mammal the two wings can be used simultaneously, which allows one for control and the other for experimental procedures.

One undesirable feature is the difficulty in obtaining bats during the entire year, and, because the animals will not eat in captivity, their survival time in the laboratory is limited to a few months. Also, histological sections are difficult to prepare for study because of the extreme thinness of the wing.

Utilization of these various techniques has resulted in the resolution of some old controversies, e.g., the role of the Rouget cell, and has clarified to some extent the anatomical structure and physiological function of terminal vascular beds. It has made many investigators aware of the danger of ascribing specific changes in blood pressure or the rate or volume of blood flow to the activity of small blood vessels, on the basis of indirect measurements. While the change in systemic pressure following some experimental procedure need not be challenged, the means by which it is brought about may be better explained

if direct observations of the vessels controlling peripheral resistance are employed.

STRUCTURE OF TERMINAL VASCULAR BEDS

From the foregoing section it is apparent that the microscopic blood vessels which connect the venous and arterial systems have been studied in a wide variety of tissues with equal variety in the choice of experimental animals. Differences in vascular patterns and structural components are to be expected, but these differences are minor compared to the more general similarities among the various microcirculatory beds. It is this aspect that will be emphasized in the following descriptions of the microcirculation.

Microcirculation in the Bat Wing

Utilization of the bat wing for studies of the structure and function of small blood vessels has a long history. An interesting and detailed report appeared in 1852, written by T. Wharton Jones (68), who described the impressive rhythmical vasomotion of the veins. Scattered publications by other investigators appeared (18, 63, 87) early in the twentieth century when new interest in capillary circulation was at its peak. The interest in the wing of the bat as a site for microscopic observation of vascular beds was stimulated in 1946, when Nicoll & Webb (88) published the results of several years of observations. A description of the vessels and their patterns in the terminal vascular beds of the wing follows.

The major site of peripheral resistance was found to be in the small arteries which anastomosed to make interconnected channels or loops. These small arteries, which arose from the main arterial plexus and formed arteriolar nets, had the capacity for changing their lumen size by vasoconstriction. The smaller arterioles of the nets usually had an inside diameter that was equal to or smaller than that of a red blood cell. Nonmuscular capillaries arose as branches of any of these vessels of the arteriolar plexus, the parent vessel of the nonmuscular capillary being designated the terminal arteriole. The muscular coat of the terminal arteriole became less regular as the vessels advanced peripherally, as did the number of muscle cells on the branches arising from it.

The pathways between the arteriolar and venous plexuses were seen to be similar to those of the rabbit ear, as described by Clark & Clark (34) and Sandison (106), with no preferential channel to carry blood

FIG. 1. Paths of blood flow in capillary bed in small area of the bat's wing. [From Nicoll & Webb (88).]

from the arterial to the venous side. Blood was seen to take alternate routes through the capillary nets. At times, especially in the terminal arterioles, there appeared to be a major path of flow through the capillary vessels to the venules, but this path was seen to be inconsistent and changed to alternate routes with modifications in arteriolar or venular circulation in adjacent regions (see fig. 1).

Supravital staining made it possible to study the arrangement of the vascular smooth muscle of the various vessels. Arteries had both circular and longitudinal muscle fibers, the latter disappearing in the arteriolar vessels. The terminal arteriole gradually lost its circular muscle investment until areas of bare endothelium could be seen and finally a single coiled muscle cell formed the precapillary sphincter. The spiral arrangement of a muscle fiber continued for a number of turns, presumably reaching a length of over 100 μ if uncoiled. Postcapillary vessels acquired a muscular coat in the region of the first valves, and thus veins were formed. Veins had the usual double layer of circular and longitudinal muscle fibers.

Because of the small caliber of arterioles and capillaries, flow was frequently seen to stop due to obstruction by a leukocyte. In some instances, an internal pressure increase would cause the leukocyte to move on. At other times, the leukocyte could be seen to

migrate slowly along the vessel wall until it reached a larger vessel where it was swept forward in the blood stream. Plugging of small vessels by leukocytes was found in normal fields with vigorous flow, and this obstruction determined to some extent the flow of blood through the capillary nets.

In 1954, Webb & Nicoll (130) discussed the angle which an arterial branch forms as it leaves its parent vessel. The downstream angle was found to approach 45 degrees. Webb and Nicoll postulate that this helps to insure almost equal pressure in the artery and the branch which arises from it. A similar type of branching is seen in the arcuate arrangement formed by arterioles. Arterioles, however, usually leave arteries at right angles. The arteriolar branches have sphincters at their point of origin that regulate the size of the lumen of the branching vessel as it leaves the artery.

The arcuate system formed by the arterioles affords collateral pathways and contributes to a uniform distribution of blood at uniform pressure within the capillaries.

The capillaries form an extensive anastomosing net which is supplied by terminal arterioles arranged in such a manner that no capillary net is very far away from its arteriolar supply.

Active vasomotion of arteriolar vessels is, according to Webb and Nicoll, the principal factor of a local nature that regulates blood flow and blood pressure in the capillary beds. The activity of the muscular wall of the arterioles, which constitutes active vasomotion, is independent of central nervous control. Degeneration of nerves supplying an area does not affect active vasomotion in the smaller arterioles, nor does stimulation of intact nerves, although this does result in a contractile response from the arteries or the larger arterioles.

Blood flow and blood pressure in capillary nets, then, are controlled by two factors, one being the anatomical arrangement of the arterioles which form arcades, and the second being the active vasomotion of the arterioles which is determined by local conditions.

Further discussion of the arcuate patterns formed by arterioles in the bat wing appeared in a report by Nicoll & Webb (89) in 1955. Arteriolar vessels form arcuate configurations. These anastomosing vessels are approximately equal in diameter. Several distinct arteriolar arcuate systems can be identified arising from either an artery or a large arteriole. Two characteristic features were found in the manner in

FIG. 2. Enlargement of an arteriolar branch at its point of origin. Bat wing. $\times 875$.

which the arcuate systems began. One was the angle of origin of the arteriolar vessels from the parent vessel, and this was found to be 90 degrees or less in reference to the forward direction of flow in the parent vessel. The second characteristic feature is a dilatation or enlargement of the arteriolar branch at its point of origin compared to its diameter throughout its length. Also, the inside diameter of the opening between the parent vessel and branch is much smaller than the average inside diameter of the branch (fig. 2). This formation, described by Nicoll and Webb in the bat wing and named "Indian Club," has not been described in microscopic vessels in other terminal vascular beds. In view of the fact that the notable appearance of the enlargement of a vessel at its junction depends to some degree on tonus, it may not be readily apparent in anesthetized animals in which vessel tone is low. If the tonus of the branch is quite low, there may be little or no apparent difference be-

FIG. 3. Arcuate patterns in the terminal vascular bed. [From Nicoll & Webb (89).]

tween the outside diameter of the branch at its junction and along its length. Terminal arterioles originate mainly from the smallest arcuate vessels, but may also arise from any of the arcuate arterioles or a small artery (see fig. 3).

The capillaries form extensive nets, and the distribution of blood within the nets from any particular terminal arteriole is limited. Local conditions, which must be considered to be a major factor of control, constantly change the paths of blood flow through the capillary bed.

Venous vessels show an arcuate pattern that roughly follows that of the arteriolar vessels. At the point where a capillary vessel joins a venule, a valve may often be seen, although in many instances no such structure is evident. Nicoll and Webb suggest that since the muscular coat of the venule begins in the immediate vicinity of the valve, this site may be considered as the true junction between capillary and venule.

The flow of blood through the capillary nets is controlled chiefly by activity of the terminal vessels. When they are dilated, flow is rapid and continuous in the capillary nets. Constriction of a terminal arteriole necessarily stops the flow of blood through the capillary vessels supplied by it. When the numerous terminal arterioles which supply an interconnected network of capillary vessels are contracting and relaxing intermittently and aphasically, the flow of blood into collecting venules may be continuous. Cessation of flow from venous capillaries into venules is often produced when resistance to inflow is met because of a closed valve at the junction of the two

converging vessels. Forward flow is seen on opening of the valve.

Nicoll and Webb offer several features of both the anatomical arrangement and the behavior of vessels in terminal vascular beds as the regulators of blood flow and blood pressure at this level. *a)* The arcuate pattern of arterioles provides a means for intrinsic regulation of flow and pressure. The roughly concentric organization of the arcuate systems, made up of anastomosing vessels of the same size, serve as volume reservoirs for capillaries. Such an arrangement assures an adequate blood supply for capillary nets which does not fluctuate widely with changes in flow and pressure in single arterial vessels. The authors consider such an arrangement to be necessary in a system in which the demand for blood varies and in which some of the distributing vessels are distensible, thus allowing increases in pressure to be absorbed in the stretched vessels rather than to contribute to increased flow. *b)* The angle of origin formed by an arteriole in reference to its parent vessel affords a means by which pressure may be abruptly reduced. Also, this manner of branching off at a 90-degree angle or more assures an adequate pressure head for each outlet from a given vessel. This arrangement, coupled with the fact that a capillary bed receives blood from several terminal arterioles, results in equal pressure in all capillaries regardless of their distance from their arterial supply. Capillary pressure, sufficient for proper function, can be maintained with minimal arterial pressure. *c)* Nicoll and Webb believe that the Indian Club formation at the arteriolar origins is most important in pressure regulation. The actual size of the orifice of each arteriole aids in reducing pressure from artery to arteriole. The variability in the size of the orifice, which depends on contraction or relaxation of the muscle cells which form it, adds another means of control of pressure in small arteries and arterioles. It is possible that the contraction and relaxation of the muscular elements at arteriolar origins is determined by intra-arterial pressure. This myogenic response would afford another intrinsic mechanism whereby the pressure and flow through capillary nets could be kept at a constant level independent of wide variations among these values in arterial vessels. *d)* Neural control of larger arteries does not seem to be important in the regulation of capillary blood flow. *e)* Active vasomotion in the terminal arterioles causes blood flow through capillary nets to alternate between very vigorous flow and no flow at all. Local conditions determine the degree and

extent of contractile activity of the smooth muscle cells which encircle the terminal arterioles, and therefore local conditions can be responsible for controlling capillary flow to meet the requirements of the tissues in the immediate environment.

Microcirculation in the Rabbit Ear

Collection of new and important data on mammalian small blood vessels began in 1924, following the introduction of the transparent chamber technique by Sandison (104). He reported (106) observations on circulation in the rabbit ear primarily concerned with contractility of small blood vessels. Local control of blood flow was seen to reside in the smooth muscle cells which developed on newly formed capillaries as they were transformed into arterioles. In observing circulation of blood through the vessels which formed in the chamber, Sandison saw an axial stream of cells surrounded by a narrow, clear plasma layer. Leukocytes were thrown into the peripheral layer of plasma and slowly rolled along the vessel wall. An uneven mixture of blood cells and plasma was observed during sluggish or irregular flow through capillary nets, this type of flow resulting from the aphasic and independent contraction of arterioles which causes blood to be fed to the veins through capillaries and venules in a broken stream. "Plasma skimming" was seen mainly in partially contracted vessels or in capillaries connecting two vessels and in which there was no circulation due to equal pressure at each end of the connecting capillary. In a capillary loop, the two ends of which were connected to a larger vessel, plasma flow (indicated by the passage of blood platelets) would continue in the absence of circulation of blood cells. An increase in the blood supply to the larger, parent vessel often caused red blood cells and leukocytes to be forced through the capillary loop. The blood cells were often seen to take long narrow shapes as they were forced through the constricted entrance to the capillary loop.

Although capillary circulation was almost entirely regulated by contraction of the arterial vessels supplying the capillary plexus, flow was seen to be slowed or even stopped by a single leukocyte caught in a constricted portion of a vessel. One of the most favorable places for plugging by a leukocyte was found to be at the origin of the small arterioles from their arteries. This region was normally partly constricted because of the bulging of endothelial cells into the lumen of the vessel. This site bears a close resemblance to the Indian Club structure described by

FIG. 4. Camera-lucida drawing of a precapillary branch of an artery. *Musc.* = muscle cells; *End. nucl.* = endothelial nucleus; *Adv.* = adventitial cell; *Cap.* = capillary. [From Sandison (106).]

Nicoll & Webb (89) (see fig. 4). The leukocytes were dislodged by an increase in force of the blood stream or by the ameboid activity of the leukocytes. A similar occurrence was seen by Nicoll & Webb (88) in blood flow through comparable vessels in the bat wing.

Clark & Clark (29), in the same year, reported on the behavior of microscopic vessels seen in the rabbit ear using a "preformed-tissue" chamber, one in which the original structures were present as opposed to newly formed vessels and nerves seen in the first studies using the transparent chamber. The Clarks were impressed with the contraction of arteries and arterioles; spontaneous rhythmical contractions as well as contractions in response to artificial stimulation (mechanical, tactile, or auditory). Spontaneous rhythmical contraction was seen to play an important role in regulation of blood flow, causing changes in the distribution of blood to different capillary areas and causing continuous alterations in the direction of flow. Contractions of arterial vessels were found to be varied. Contraction of the main artery reduced the blood flow to the whole area, but the distribution of blood to different portions was dependent on contractions of different arterial branches, each at a different tempo and independent of the contraction of the main artery and of each other. An arteriole might contract to complete closure and thus cut off blood to the capillaries it supplied while an adjacent vessel, a branch from the same artery, would remain open to allow rapid passage of blood. Arteriovenous anastomoses were seen to contract actively and so influence the distribution of blood. Contractions were seen to decrease in animals that were asleep or anesthetized.

Further studies on the activity of arterial vessels,

including arteriovenous anastomoses, appeared in 1934 (30). Clark and Clark again described the fluctuation in rate and amount of blood flow through any given vessel, as well as the frequent reversals in the direction of flow. A single capillary or venule was seen to have an abundant flow of blood in one direction and a few seconds later an equally great flow in the opposite direction. The variation in flow included scanty flow of a few blood cells, or plasma and platelets only, or stasis, or complete emptying. Such changes were brought about by periodic active contractions of arterial vessels or portions of arterial vessels. The numerous thick-walled arteriovenous anastomoses were most conspicuous for their active contractility. Their contractions were usually more frequent, quicker, and more powerful than those of the arteries, and their effect on venous circulation was more sudden. Definite active contraction of veins was reported to occur near the point of entrance of a cluster of arteriovenous anastomoses.

Clark & Clark (32) studied the growth of capillaries into a transparent chamber and found that new capillaries arose as endothelial outgrowths from vascular endothelium. They advanced as blindly ending sprouts, connecting with neighboring sprouts to form loops, and continued to advance as a plexus with a growing edge of new sprouts. The growing vascular network showed differentiation of vessels in the older portions of the first-formed capillary plexus and many of the capillaries were seen to retract and disappear. An entire chamber was revascularized in 2 or 3 weeks with further differentiation continuing through enlargement of new arterioles which were receiving a large blood supply and widening of venules draining large amounts of blood. There was a further reduction in surplus capillaries. After a few days, the vascular pattern was relatively stable.

The Clarks next directed their attention to the development of extra-endothelial cells on the walls of peripheral blood vessels (33). Three months after vessels had regenerated it was found that venules were wider than capillaries, both vessels having similar walls, while arterioles were as narrow as capillaries and narrower than venules. The walls of the arterioles differed in number and arrangement, and in the form of the extra-endothelial cells. Blood flow was seen to be steady and rapid in arteries and arterioles, steady and slower in veins, and slow with frequent hesitations and reversals in capillaries. Circulation in capillaries was variable, with intervals of steady flow being interspersed with periods of stasis, plasma

skimming, or absence of flow during which the vessels remained open and were filled with plasma. The subsequent fate of the extra-endothelial cells depended on the fate of the vessel on which they appeared. If the vessel remained a capillary, they were occasionally seen to increase in number by mitotic division or to retain the same number. The cells were inert. If the capillaries became parts of venules, the adventitial cells increased in number, retained their longitudinal arrangement, and remained inert. The change of a capillary to an arteriole involved straightening of the vessel, loss of side branches, narrowing of caliber, and an increase in thickness of the endothelium. There was a rapid increase in the number of extra-endothelial cells which assumed a transverse position. Definite active contractility was seen to develop in these cells which became smooth muscle cells, providing they were reached by a regenerating vasomotor nerve.

The caliber changes in minute vessels were discussed by Clark & Clark (34) in 1943. In earlier published studies, the attention of the authors had been on the main arteries, their branches, the arteriovenous anastomoses, and the larger veins. Observations on newly formed arteries indicated that the number of arteries which developed contractility, the rate at which contractility appeared, and its final extent on individual vessels and their branches depended on the rate and extent of growth of new vasomotor nerves. Terminal arterioles in original vascular beds in the preformed type of chamber were seen to show spontaneous contractions which in most cases obliterated the lumen. These vessels could sometimes be made to contract by prodding the animal, but their behavior was erratic. A terminal arteriole was seen to divide immediately beyond its last muscle cell into a capillary plexus. In some instances a terminal arteriole was prolonged for a distance beyond the point of the final muscle cells before forming a capillary plexus. Such vessels had longitudinally arranged adventitial cells rather than muscle cells on their walls. Except for this, they had the characteristics of arterioles, being straight, uniformly narrow, and having a relatively thick endothelium. The region of active contraction was confined to the portion of the vessel which had smooth muscle cells, but the distal portion at times showed a narrowing, with protrusions of endothelial nuclei into the lumen, after blood flow was shut off by active contraction of the proximal portion of the vessel. The vessel showed an increase in caliber following increased blood flow through it. The Clarks refer to these vessels as arterial capillaries.

Microcirculation in the Mesentery

Early descriptions of mesenteric circulation patterns by Zweifach (143) and Chambers & Zweifach (20) dealt primarily with establishing a structural and functional unit, the preferential or thoroughfare channel, which was thought by the authors at that time to be a representative structure of terminal vascular beds. A discussion of the vascular components of the mesenteric circulation and blood flow through them appeared in 1954 (147). Zweifach stated that the mesentery represented a simplified vascular structure devoid of ancillary features peculiar to specific organs. In observing normal circulation in the rat mesoappendix (cecal mesentery), Zweifach found the larger arteries along one side of the mesentery to be about one-third as large in diameter as their paired veins. The depth of anesthesia influenced the caliber of these vessels, deep anesthesia causing them to dilate until both vessels had the same diameter. Respiratory difficulties caused venous constriction. Terminal arterioles in the mesentery proper had a very rapid flow of blood. Collecting veins had a steady flow of blood with continuous forward flow without cessation or temporary reversal. Capillary circulation, however, showed intermittent flow produced by the contraction of precapillary sphincters, the activity of which was irregular and unpredictable. Preferential channels were found to be unusually prominent in the mesentery. The most important structural component for regulating capillary blood flow was the precapillary sphincter. The precapillary sphincter was found at the junction of all offshoots of the muscular components of the vascular bed. The true capillary network was made up of endothelial tubes with no perivascular muscle cells. In some areas the collecting venules were formed by the joining of several side branches leading from precapillary sphincters. Both terminal arterioles and venules were seen to be interconnected to form a series of arcades, so extensive in some cases that they completely circumscribed the capillary bed. The metarterioles originated as offshoots of the arteriolar arcades, extended toward the center of the tissue distributing typical precapillary branches. The arteriolar channels terminated as one or two short capillaries which fed directly into a venous vessel. Zweifach expresses the opinion that the primary mechanisms which readjust circulation through the capillary bed are essentially of a humoral nature. Neurogenic mechanisms, local metabolic factors, and blood-borne substances from organs contribute to the local regulation.

Microcirculation in the Hamster Cheek Pouch

The use of the hamster cheek pouch for microscopic study of the peripheral circulation was introduced by Fulton *et al.* (50, 51).

Although there is no detailed description by these authors of the basic vascular pattern that is seen in this mucous membrane, the literature contains references to the presence or absence of various vascular structures which will be presented here.

The cheek pouch is exceedingly vascular compared to rat mesentery or membranes in transparent chambers. The pattern differs also from the mesentery in that no preferential channels have been found. A rich network of anastomoses between venous vessels and arteriolar vessels is present. Arterioles, which supply the capillary network, bifurcate progressively into branches of equal significance for the distribution of blood (fig. 5). The arterioles exhibit spontaneous vasomotion (80, 82). Lutz & Fulton (81) state that precapillary sphincters were seen to contract independently of adjacent smooth muscle in cheek pouch vessels. Intermittent flow from small veins was also seen, but no venous sphincters were identified.

Lutz & Fulton (81) point out that there is always variation in the demand for blood by the organs, and this variable demand can be satisfied by vasomotor responses without involving the heart or other large structures. The complex anastomosing system of vessels in the cheek pouch, for instance, coupled with vasomotion, permits changes in flow. Neither the vessel wall nor the flow are ever quiescent, the most striking feature of the small vessels being their constant activity.

More vein-to-vein than artery-to-artery anastomoses are seen in the hamster cheek pouch. Venules make up the greatest amount of endothelial surface and contain the greatest proportion of circulating blood at any one time. Lutz and Fulton believe that 60 to 70 per cent of the peripheral circulating blood is in the venous vessels.

Poor & Lutz (97) studied the functional anastomotic vessels in the cheek pouch and reported that artery-to-artery anastomoses were generally one-third to one-half the size of the parent arteriole. These were outnumbered by the vein-to-vein anastomoses. The venous anastomoses were nearly the size of the veins which they connected (fig. 6).

Microcirculation in Skeletal Muscle

The description of the distribution of minute vessels in skeletal muscle has not changed to any marked

FIG. 5. Vascular pattern of the hamster cheek pouch. (Courtesy of Dr. E. P. Fowler, Jr.)

FIG. 6. Vascular network of hamster cheek pouch near buccal end, lead chromate injection. [From Poor (97).]

degree in the last eight decades. The early information comes from studies of injected and fixed material, and in recent years there have been investigations using microscopic techniques on living animals.

Krogh (73) reviews the work of Spalteholz (116), who depicted the vascular arrangement as follows: freely branching arteries with numerous anastomoses between the branches form a primary network which in turn gives off anastomosing small arteries that form a second network. Arterioles branch from this network, usually at right angles to muscle fibers at regular intervals. The arterioles then split up into a large number of capillaries which run along parallel to the muscle fibers with numerous anastomoses. The capillaries unite into venules. The pattern of the venous system is almost exactly that of the arterial systems.

Clark (37) and Walls (126) state that skeletal muscle, which is highly vascular, is supplied by branches from neighboring arteries which invade the epimysium and travel into the perimysium, dividing

as they do so. Various branches of the vessels entering the perimysium anastomose with one another. The finer branches lie transversely to the long axes of the muscle fibers and give rise to the capillaries which run parallel to the muscle fibers. These parallel capillaries lie in the endomysium. This, then, is the anatomical sequence: arteries and veins run together until terminal arterioles and venules are reached. The terminal arterioles and venules then come off of the parent vessels in alternate sequence. The capillaries, running longitudinally between muscle fibers, are connected frequently by transverse vessels which run over or under the intervening fibers and thus form a fine capillary network of tiny oblong meshes.

Zweifach & Metz (151, 152) have studied the vascular supply of the spinotrapezius muscle in the rat. Their observations were primarily of vessels in the epimysium and the perimysium. They found two distinct components in the capillary circulation of muscle bundles, 1) a vascular bed that was distributed along the natural cleavage planes in the connective tissue sheath that binds collections of muscle bundles together, and 2) a second capillary network originated by short muscular arterioles which penetrate into the

depth of the muscle proper and terminate by branching into numerous capillaries.

There are impressive numbers of anastomoses between both arterial and venous vessels which form a series of arcades. Direct anastomoses between arterioles and venules are also found.

The capillary bed of the perimysium is supplied by metarterioles which come off at right angles from the arterial or arteriolar arcades. These metarterioles terminate as one or two capillaries which unite with other capillaries to form venous effluent vessels. The capillaries lie directly on the surface of the small muscle bundles, thus each muscle bundle is surrounded by a network of arterial and venous vessels which interconnect freely with one another within the connective tissue separating the bundles. The muscle fibers are supplied with blood by branches from the arteriolar arcades which penetrate the connective tissue and give rise to capillaries which run along the length of the muscle.

Zweifach and Metz report the presence of metarterioles along the free margins of the skeletal muscle which can be traced directly to the venous system. These vessels, they believe, represent preferential pathways which convey the most rapid stream of blood from the arterial to the venous side.

In addition to structural features, spontaneous vasomotor changes were seen by Zweifach and Metz in arterial and venous vessels. The vasoconstriction was not often intense enough to stop blood flow through the vessels involved, except at the level of the pre-capillary sphincters.

In investigations of red and white skeletal muscle in rabbits (75, 113) injected preparations showed arterial vessels which branched profusely to end in capillaries running parallel to muscle fibers. Also shown were numerous anastomotic connections between small vessels.

Algire (4) and Algire & Merwin (5) studied the panniculus carnosus through a transparent chamber in the rat's back and also saw many arterial anastomoses as well as arteriovenous anastomoses. Arterial branches from the subcutaneous layer supplied the thin striated muscle layer with blood. The arterioles from these branches subdivided into capillaries which ran parallel to the muscle fibers, with cross connections between them, joining other capillaries to form collecting venules.

The capillary blood flow was noted to be intermittent, the result of active vasomotion of the arterioles. Algire & Merwin (5) estimated the length of capillaries that were seen between the muscle fibers

FIG. 7. Capillary vessels in skeletal muscle.

to be between 0.3 and 1.0 mm, with anastomoses occurring at intervals of about 0.1 mm.

Observations of the capillary network of the skeletal muscle bands that course through the bat wing show a vascular pattern similar to the descriptions given above (see fig. 7).

There are notable differences between the distribution of capillaries in the endomysium and that in the areas adjacent to the skeletal muscle. The vessels which run parallel to the muscle fibers are generally longer and straighter than comparable vessels in the surrounding connective tissue. An arteriolar branch that crosses the muscle fibers often subdivides into two capillaries that originate at right angles to the parent vessel and go off in opposite directions. They usually do not lie in the same plane, one going deep between the fibers, occasionally until lost from view, while the other vessel continues on the upper surface. As a result of this downward, or sometimes upward, turn it is possible to look directly down into the lumen of a capillary rather than at the customary longitudinal view. An arteriole with its accompanying venule may cross the muscle band without either of the vessels

FIG. 8. Red blood cells "on edge" in a capillary of skeletal muscle.

giving off branches to contribute or to receive blood from the underlying muscle. When capillary vessels running parallel to the muscle fibers are confined to the narrow space between two fibers, the capillaries are flattened and the cells face the fibers (fig. 8), as reported by Reynolds *et al.* (100) in similar vessels in the myocardium. In a wider space, the cells are often seen broadside.

Anastomoses between the capillary vessels running parallel to the muscle fibers are numerous, the connections occurring sometimes between adjacent vessels and just as frequently with vessels lying some distance away. Short connections between arterial and venous pathways are also seen.

Intermittent flow occurs in the capillaries of these skeletal muscle bands as a result of spontaneous closure of short duration of terminal arterioles that give rise to the capillaries which lie in the endomysium.

Studies made thus far in these beds have established no characteristic pattern formed by vessels supplying the muscle bands that deviates from what is normally

seen elsewhere, except for the parallel course of the vessels lying between the muscle fibers.

Microcirculation in Myocardium

There is a paucity of descriptive literature on the capillary beds in the myocardium. Although a few investigations on fixed material appear, no studies have been made on circulation through the minute vessels in the living animal, presumably because of the difficulty of microscopic observations of an organ in motion.

In 1928, Wearn (127) studied sections of myocardium obtained from man, cats, and rabbits. The vessels were filled with material injected through coronary arteries. Wearn observed that almost every cardiac muscle fiber was in direct contact with one capillary and some fibers were touched by two or more. A muscle fiber was completely surrounded in some instances due to numerous anastomoses between capillaries. These interconnecting branches ran across the parallel muscle fibers. Capillary vessels were found to lie between the cardiac muscle fibers and did not actually penetrate the muscle substance.

Saunders & Knisely (107) reported having watched through a microscope the circulation in the myocardium of beating frog hearts. Blood flow was seen to stop during systole and to flow profusely during diastole. The cessation of flow in systole was brought about by compression of the small vessels by the contracted myocardial fibers.

Reynolds *et al.* (100) studied fixed sections of heart muscle, the hearts having been taken from dogs without loss of blood from the coronary vessels. They report that capillaries had a diameter of approximately $4\ \mu$. The capillaries were seen to run along the muscle fibers as described by Wearn (127), about one capillary to every muscle cell. The orientation of the red blood cells within the capillary vessels was believed to be unusual, in that the cells were often seen edgewise, i.e., with the flat surface of the red cell facing the parallel myocardial fibers. The authors conclude that the capillary vessels running between the muscle fibers are elliptical in cross section rather than round.

In normal hearts, more capillaries were found in the epicardium than in the middle portion or the endocardium. Various explanations, none conclusive, were given for this.

Terminal arterioles were identified by the presence of an endothelium with distinguishable smooth muscle cells along their walls. The terminal arteriole gave rise

to a number of capillaries that ran parallel to each other in the same direction as their parent vessel.

A postcapillary venule was formed by the union of capillaries which came from opposite directions along the muscle fibers. The postcapillary venule increased in size as it was joined by similar tributaries. These tributaries formed venules, which were identified by their muscular walls.

Provenza & Scherlis (99) studied sections made from dog hearts and placed great emphasis on the appearance of "muscle sphincters" in various small vessels. Although the authors have used the terminology of Chambers & Zweifach (20), it has not in every instance been properly applied, and comparison with other terminal vascular beds is difficult. A highly imaginative diagram indicates the presence of arteriovenous anastomoses, metarterioles, thoroughfare channels, and precapillaries.

Microcirculation in Skin

Zweifach (149) has presented a description of the cutaneous circulation in a flap of skin of the rat from which the connective tissue had been cleaned off.

A network of arterial vessels in the connective tissue between the skin and underlying muscle gives rise to small arteries which enter the dermis. These small arteries, as well as the ones from which they originate, form a regular pattern of interconnecting links or arcades. The capillary bed of the dermis is composed of a secondary network lying between the interarcading arterioles. This secondary network is formed by precapillary and capillary vessels that are branches of the interarcading arterioles.

Blood flows away from the capillary bed in wide vessels, which join to form collecting venules. The collecting venules form an interconnecting plexus that is similar to, but more extensive than, the arterial plexus. Many short arteriolar branches are seen to go directly into the vessels of the venous plexus. Also seen are direct connections between arterial and venous arcades that allow blood to go from arterial to venous side without going through a capillary network. The venous vessels form the major portion of the cutaneous vascular beds.

Zweifach believes that the branches which leave the arterial arcades are structurally similar to metarterioles in that they have a thin layer of smooth muscle and a comparatively straight course. The vessel finally becomes part of the capillary bed after giving off branches along its course. These offshoots, or side branches, are precapillary vessels, having

spirally arranged muscle cells in the immediate junctional region. The precapillary vessels show characteristic spontaneous vasomotion. Vasomotion is also seen in the deeper lying arterioles. The small venules of the cutaneous bed show a continuous almost rhythmic pattern of spontaneous activity that is unrelated to the vasomotion of the deeper lying vessels.

The arteriolar arcades were found to be very responsive to constrictor and dilator agents. The venous arcades showed a 20-fold increase in responsiveness to epinephrine when the temperature was made to fall 1 or 2 degrees, indicating that they are greatly influenced by temperature change. Zweifach considers the venous network in the skin to be unique in this regard.

From his studies, Zweifach concluded that the structural pattern of the cutaneous circulation was atypical, since it was composed predominantly of highly reactive venous vessels. The circulation in the skin appeared to be regulated locally by tissue mediators.

The description of the cutaneous vascular pattern and its vasomotion conforms in most respects to that of other terminal vascular beds that have been studied, with the possible exception of the mesentery and the omentum. The interconnecting arcades of both arterial and venous vessels with a secondary network forming the capillary bed are prominent features of the pattern of small blood vessels in the hamster cheek pouch and the bat wing. Such an arrangement seems to be a common denominator in vascular patterns of the microcirculation.

Microcirculation in Stomach and Intestine

Until a recent paper by Baez (6), descriptions dealing with the vascular patterns of small blood vessels in the stomach and intestine have been based on injected and fixed material. It is extremely difficult to establish the paths of blood flow in a tissue without observing the flow in living material. This would apply especially in such a vast network of venules and arterioles which intercommunicate so freely by a system of arcades as is present in the musculature of the gut. Although the early investigations briefly discussed here are not concerned with the smallest vessels, they will serve as a background for a more detailed description of the terminal vascular beds of the alimentary canal.

Noer (90) studied the vascular patterns in the jejunum and ileum of specimens prepared by liquid latex injections. The descriptions are of the mesenteric circulation and the superficial vessels of the gut wall

FIG. 9. Types of antimesenteric area anastomoses. [From Noer (90).]

(the mural trunks). In his search for an experimental animal which might have a vascular distribution similar to man, he observed 14 different animals. The basic architecture was found to be similar in all animals in that the intestinal arteries formed mesenteric arcades or arches which in turn gave rise to vasa recta, which then proceeded to the intestinal wall to form mural trunks. Striking variations in the numbers of mesenteric arcades were found among the species as well as differences in the pattern of the vasa recta, including their length and whether or not they had anastomotic connections with one another. The mural trunks in the human stomach were found to ramify in two ways, a similar arrangement being seen in other animals. A single vessel passing to the antimesenteric area might give off lateral branches along the way, or the vessel might break up into several branches rather quickly and subdivide in an arborescent fashion. Three types of anastomoses between the mural trunks in the antimesenteric area were found to be 1) direct communication between the mural trunks of the two sides, 2) a plexiform arrangement, 3) short vessels joining arcuate mural anastomoses (fig. 9). Veins were found to follow the arteries with few exceptions.

Although Noer was not the first to describe the arcuate patterns found in the arterial and venous vessels of the intestine, his report is extensive and detailed, and contains a comprehensive review of the literature up to that time.

Investigations of the alimentary tract during the next few years centered around the absence or presence of arteriovenous anastomoses, especially in the human stomach. Barclay & Bentley (7), stimulated by the findings of Trueta *et al.* (120) of vascular shunts in the kidney, proposed that in the wall of the stomach there were arteriovenous anastomoses in the region of the submucous plexus, and that when these arteriovenous anastomoses were open, active circulation through the vessels of the mucous membrane was

excluded. Their conclusions were based on the absence of radiopaque material in the mucous membrane of stomach injected immediately after surgical removal. They suggest that the injected material flowed from arteries of the submucosal plexus to the gastric veins directly through a shunt located in the submucous plexus. In 1952, Walder (125), accepting the presence of arteriovenous anastomoses in the submucous layer of the human stomach after what seemed to be confirmation of them by Barlow (8) through microdissection, carried out investigations to determine their function, size, and responses to stimuli, both physical and pharmacological. Cannulation of the right gastroepiploic artery and its accompanying vein permitted him to introduce glass beads, 40 to 200 μ in diameter, into the artery and to recover them in the venous outflow. The presence of spheres, 140 μ in diameter, in the venous outflow was believed to be indicative of patent arteriovenous anastomoses, because spheres of this size could not travel through the capillary network. The results of the injection of drugs, nerve stimulation, and varying perfusion pressures to determine their influence on the size of the arteriovenous anastomoses were inconclusive.

In an extensive study of the vascular patterns in the alimentary canal, Barlow (8), in describing the arterial supply to various portions of the stomach, notes frequent anastomoses of the arteries in the submucous plexus and the mucosa. The mucosal arteries give rise to capillaries which also have anastomotic connections. He found arteriovenous anastomoses in the stomach which consisted of an arterial end, variable in length, a short narrow junction area, and a short wide venous channel. This structure was demonstrated by Barlow's double injection technique. The arterial end may be a direct branch of a mucosal artery or arise from a main channel in the submucous plexus. It terminates by joining either a distant mucosal vein or may double back on itself and anasto-

[From Barlow (8).]

mose with a tributary of its accompanying vein (fig. 10).

In 1959, Baez (6), using the small intestine of the rat, gave a detailed account of the vasculature at various levels based on observations in the living animal. In discussing the method of observations, Baez points out the advantage of having an intact animal in which the distribution of large supplying arteries and accompanying veins of the wall as well as their relation to the small vasa recta can be determined. The type of a vascular connection at the antimesenteric border as well as the vessels of the submucosal plexus and the final ramifications of the vessels to the muscular coat can be established.

The description of the vessels in the submucosal plexus is as follows: Main arteries ($60\text{--}80\ \mu$), which pierce the muscularis in the mesenteric region at intervals, divide into two or three branches in the submucosa. Each branch subdivides into four or six smaller branches ($30\text{--}40\ \mu$) which then proceed to the antimesenteric border where they connect with similar arterial branches from the other side. Other arterial anastomoses are formed by interconnections of branches between neighboring recta. Baez uses a general description for main arterial arcades with three characteristics: 1) they are located in the outer plane of the submucosa and average 30 to $40\ \mu$ in diameter; 2) all give rise to secondary arcades, mucosal arteries, and vessels to nourish the muscular coat; 3) the direction of blood flow through them is changing constantly.

The small vasa recta which arise from the last

mesenteric arcade terminate quickly by anastomosing with secondary branches of other arcades. The small vasa recta lie between the large vasa recta. They supply the vessels to the submucosa and muscular coats of the gut wall near the mesenteric border (fig. 11). These vessels go in opposite directions, some to the outer smooth muscle coat and others to the inner absorptive surface of the gastrointestinal tract. They seem to have a unique type of blood flow. Unidirectional flow in the large and small vasa recta is altered in the meshwork of interconnected arterial vessels in the submucosal plexus. A main arterial arcade may show complete reversal of flow or, as more frequently happens, blood may flow from both sides of an arterial arcade into a mucosal artery. At times, when blood is rushing into an arcade from opposite directions, the converging currents may produce a space of clear plasma at the point where they meet. When this occurs at the origin of a mucosal vessel, plasma is "skimmed" into it.

The muscular coat of the ileum is supplied by vessels that originate from the proximal end of mucosal arteries or from secondary arcades in the submucosa. Baez considers these vessels to be metarterioles, 18 to $24\ \mu$ in diameter, which enter the muscularis and run in the plane of cleavage between the circular and longitudinal muscle bundles. In the intermuscular septum the capillaries for the circular muscle bundles stay on the same plane as the parent vessel, while those for the longitudinal muscle bundles turn outward. The capillaries communicate freely to form a network, both in the same plane and

FIG. 11. Photomicrograph from the anterior wall of rat ileum. (Courtesy of Dr. Silvio Baez.)

between adjacent layers of muscle. The parent vessel either divides in two, or arches and becomes a venule which is joined by venules from neighboring capillary nets before entering a submucosal vein. Such an arrangement, whereby a metarteriole leaves the submucosa and enters the smooth muscle coat where it gives off a capillary network and then returns to the submucosa as a venule, constitutes, according to Baez, a distinctly organized terminal vascular unit.

The minute vessels of this unit are both muscular and nonmuscular, the muscular component being the centrally located metarteriole and the precapillary vessels which branch from it and in turn give rise to the nonmuscular capillary network. The muscular vessels and their parent metarterioles are considered by Baez to be the most highly reactive of the mural vasculature, a fact demonstrated by vasoactive drugs and varying intraluminal pressures. The capillary bed of the muscular coat of the gut, which is served by these metarterioles, shows periodic changes in blood flow; the changes being independent of flow

through the arterial plexus of the submucosa. The muscular coat may be devoid of circulation while blood continues to flow through arteries of the submucosa and mucosa.

In some instances the parent vessel may begin as a short arteriole, rather than a metarteriole, which in turn then gives rise to several metarterioles when it reaches the muscular coat. The pattern of distribution is then the same as described above; the metarteriole forms a central channel, and turns inward to become a venule or breaks up into two or three capillaries.

The mucosal artery continues toward the muscularis mucosa after having given off the vessels just described which go to the outer muscular coat. One or two short vessels are now seen to branch from the mucosal artery. The short vessels subdivide into several capillaries which reunite as a venule and empty into a submucous vein. Deeper in the submucosa all mucosal arteries anastomose with a similar mucosal artery and give rise to one or two branches which in turn subdivide to form capillary nets. The mucosal artery terminates by penetrating the base of a villus.

Baez was unable to find any arteriovenous anastomoses in the submucosa of the jejunum or ileum. It was possible to follow all the arteries and arterioles of the submucous plexus to their finest ramifications without observing any short cuts from the arterial to the venous side. This was also true in vessels in the muscular coat. He does elaborate, however, on the direct connection between arterioles and venules at the bases of villi. While the arterial component does deliver arterial blood directly to the venule which drains the villus, it cannot be called a true arteriovenous anastomosis in that the arteriole gives off branches to neighboring structures. The location of these vessels is the same as the location of vessels described by an earlier investigator (117) as arteriovenous anastomoses. Baez points out that in an injected and fixed preparation the capillary offshoots might be closed, giving the appearance of a true arteriovenous anastomosis.

Two or three venules from adjacent villi were seen to converge to form a mucosal venule. The mucosal venule also was joined by an arterial capillary which originated as a branch of the nearest mucosal artery. The small vein thus formed then emerged into the submucosa where it was joined by other veins of similar origin to form an intricate anastomosing arcade. These submucous arcades were further enlarged by venules from the outer muscular coat. The flow of blood through the venules of the muscular

coat and the mucosal venules was rapid and unidirectional. Backflow of blood was observed in veins of the submucosal plexus.

Microcirculation in the Bulbar Conjunctiva

The bulbar conjunctiva is a highly vascularized transparent mucous membrane on the anterior surface of the eye. It extends from the palpebral conjunctiva, which lines the eyelid, to the cornea. The pattern of its blood vessels were derived primarily from studies by Grafflin & Corddry (56) and Lee & Holze (77).

A description of the arrangement of the superficial blood vessels of the human conjunctiva is given by Lack *et al.* (74) in a study designed to observe vascular changes in hypertension. Arterioles were seen to divide into numerous side capillaries and terminate with an end capillary. The term "end capillary" is not defined. The end capillary on occasion functioned as a "through-and-through" channel. The capillaries appeared to be uniform in caliber. Only rare arteriovenous anastomoses of the short type were seen.

A more detailed description appears in a paper by Lee & Holze (77) in 1950, in which they state that the arrangement of terminal arterioles, capillaries, and venules in the human conjunctiva was in accord with the pattern of vessels as seen in the omentum and mesentery of other animals, referring to the descriptions of Chambers & Zweifach (20) and Lee & Lee (78). Capillaries arose at intervals from end arterioles to form an irregular network of vessels which then rejoined to form the venular system. The arterioles were also seen to terminate in main channels which communicated directly with a venule. This pattern was most often seen at the corneoscleral junction. It was also noticed that blood continued to flow from arterioles to venules, through the patent arteriovenous channels, at a time when there was widespread arteriolar and precapillary constriction. The precapillaries were found to be more sensitive to stimuli than their parent arterioles.

Observations of blood flow revealed active contraction of vessels. Constriction of precapillaries was seen to occur at their point of origin from the parent arteriole. Attention was directed to these precapillary sites because of the difficulty in determining minor changes in diameter or flow in the arterioles. Complete constriction occurred at the precapillary region lasting for 2 to 3 min. After a gradual relaxation, blood flow continued for 1 to 5 min before the next constriction. The periods of constriction and relaxa-

tion were found to be very irregular, with relaxation predominating.

Arteriolar flow was rapid, capillary flow was slower, and also intermittent due to spontaneous changes in diameter at the precapillary sites, while venous flow speeded up after entering the system of collecting venules and was consistently regular.

The proposal of a definite structural and functional unit, such as the preferential channel, as described by Chambers & Zweifach (20) in the rat mesentery and seconded by Lee & Holze (77) in the human conjunctiva, prompted Grafflin & Bagley (55) to reinvestigate the human conjunctiva. These investigators were impressed by an endless variety of vascular patterns with no apparent plan of organization. This paper was followed by one by Grafflin & Corddry (56) who reinvestigated, with improved equipment, the architecture of vascular beds in the human conjunctiva in an effort to resolve the differences between the earlier observations and those of Lee & Holze (77). Once again they reported a great variety of vascular patterns with the lack of any recognizable structural and functional unit similar to that proposed by Chambers & Zweifach (20). They saw, however, vessels between arterial and venous channels that were larger than capillaries. They believed that these vessels were arteriovenous communications with a functional significance different from that of capillaries. They do not say what the difference is. The arteriovenous communications were seen so frequently that the investigators believed that they were a characteristic feature of the conjunctival vascular beds. In freehand drawings at magnifications up to 80 times, a variety of vascular patterns are shown. The arteriovenous communications, veno-venous anastomoses and arterio-arterial anastomoses are common features (fig. 12). Although at first glance the vascular pattern may seem very complex, it is comparable in its arrangement to other terminal vascular beds which have been presented in such detail covering a large area. A smaller area is seen in figure 13.

A representative type of arteriovenous anastomosis, as seen in vascular beds below the surface of the conjunctiva (presumably on the episcleral surface), is shown in figure 14. It bears a striking resemblance to both photomicrographs and diagrams of the vascular bed in the rat mesoappendix. The authors do not describe the kind of blood flow through these vessels which would qualify them as preferential channels on a functional basis.

The vascular patterns presented by these authors

FIG. 12. Superficial vascular pattern, temporal quadrant, right eye. [From Grafflin & Corddry (56).]

may be considered to contain all the blood vessels in the areas under observation. While the walls of capillaries were never seen and their detection is dependent on the presence of blood in the vessels, it is unlikely that the same vessels would be devoid of blood consistently over a period of months during which repeated observations were made.

Vasomotion was a prominent feature of flow in the vessels of this mucous membrane. It was indicated by variations in the speed of flow, alterations in the caliber of individual vessels, and intermittent blood flow through capillary vessels. Arterial vessels usually

FIG. 13. Superficial vascular pattern, nasal quadrant, right eye. [From Grafflin & Corddry (56).]

had a rapid and continuous flow. At times the arterial vessels showed irregular alterations in the rate of flow, a reduction in the speed occurring sometimes gradually, sometimes abruptly, and sometimes stopping completely for a brief interval before surging forward.

Concerning small arteriovenous communications, there are three criteria to distinguish them from true capillaries: 1) a larger caliber than capillaries, 2) vasomotion, 3) continuous flow at variable speeds. However, one or all of these criteria might be unsatisfied on occasion. Grafflin & Corddry (56) were unable to detect precapillary sphincters at the points of emergence of true capillaries from the arteriovenous channels. It may be assumed that this failure was due to the limitations of the technique, in that the walls of the small vessels were not seen distinctly.

Venous flow is described as being continuous at a relatively moderate speed with irregular alterations in flow. At times the flow stopped completely. This does not concur with the description given by Lee & Holze (77), who reported venous flow as consistently regular.

Bloch (15), in a lengthy article dealing primarily with red cell aggregates, describes arterioles and venules in the bulbar conjunctiva in the following way: Arterioles in the bulbar conjunctiva do not differ from arterioles in other tissues. As elsewhere,

FIG. 14. Prominent arteriovenous anastomosis lying below the superficial layer of the conjunctiva.
[From Grafflin & Corddry (56).]

arterioles are most readily identified by noting the direction of blood flow. The direction of flow in these vessels is toward progressively smaller vessels, and the smallest of them empty into the capillary bed. Bloch states that when there is a low blood volume, only one capillary may be seen connecting the arterial and venous systems. The arterial segment of this single vessel has a more rapid rate of flow through it (does not say more rapid than what), differs in regard to the direction of taper of its walls (presumably larger at the venous than the arterial end), and is less permeable than the venous segment (no basis given for this statement).

Bloch feels that the difficulty in determining which vessel is an arteriole has arisen partly because of sudden changes in the direction of flow. According to Bloch, changes in direction occur when an arteriovenous anastomosis opens, causing flow in the peripheral segment of the arteriole to stop while flow in the central portion of the venule speeds up. He states that there is no difficulty in recognizing the cause of this directional change if the arteriovenous anastomosis opens while the observer is watching and when the site of the arteriovenous anastomosis can be found. He further states that usually the site of the arteriovenous anastomosis is not identified.

Linear velocity of arterioles is greater than venules of corresponding diameter. The course of the arterioles is straight compared to the relatively sinuous course of the accompanying venules. Arteriolar branches arise gradually from their parent vessels, while venules branch more nearly at right angles. Arterioles are deeper in the tissue than corresponding venules, their flow rates being so rapid that individual cells cannot be recognized.

Capillaries are described as cylinders, in contradistinction to arterioles and venules which are cones.

Some difficulty arises in comparing the descriptions of the vascular structure as given by Bloch with that of other investigators due to the absence of detailed diagrams. True arteriolar branches are not represented in other vascular beds as branching

gradually, although this type of branching occurs in vascular nets forming arcuate systems.

Microcirculation in the Spleen

Differences of opinion regarding the manner in which blood is conveyed from terminal arterioles to collecting venules in the spleen still exist in spite of the continued efforts of numerous investigators to resolve the controversy. Current histology textbooks (9, 112) present three views. The theory of closed circulation is that blood in the spleen flows through completely endothelium-lined pathways from its entrance into the spleen through the splenic artery to its exit from the spleen through the splenic vein. The theory of open circulation proposes that arterial terminations in the spleen pour blood flowing through them into the interstices of the reticulum of the red pulp. The walls of the venous sinusoids are incomplete, having longitudinal slits between the reticular cells which make up the lining of the sinuses. A third view is a compromise between the open and closed systems in that some of the capillaries are thought to open into the intercellular spaces while others open directly into the sinuses.

It was hoped that the introduction of a technique which permitted observation of the spleen of a living animal might settle the controversy. In 1936, Knisely (69) studied living transilluminated spleens of mice, rats, and cats and reported that each vessel traced in the spleen was connected to the arterial system and the venous system. No vessels were seen to open out into or pour blood into intercellular pulp spaces. The lining of the arterioles, arterial capillaries, capillaries, venous sinuses, and venules was readily apparent through the microscope as a narrow, clear, sharply refractile line, visible also during periods when no blood was flowing through the vessels. Knisely's conclusion was that the vascular system of the spleen consisted of a series of completely interconnected, preformed, lined channels. He describes spontaneous vasoconstriction in the arterial branches

as well as in the venous sinuses, and assigned this normal activity of vascular smooth muscle to "physiological sphincters." No significant differences were noted in the structure or activities of living mouse, rat, and cat spleens.

In 1941, MacKenzie *et al.* (83) reported that they had been unable to confirm Knisely's findings. They point out that the modern consensus favored a splenic circulation that had an open component which allowed flooding of the pulp interstices with whole blood, and additional pathways afforded a closed circulatory component. The reception of Knisely's investigations had been favorable and "offered a reasonable conclusion to an otherwise apparently interminable discussion." However, they were not able to see what Knisely had seen. In transilluminated spleens of mice, the walls of follicle arteries were seen as sharply refractile lines, running parallel, the diameters of the vessels uniform except when constriction occurred. The follicle arteries branched two or three times to form penicilli, synonyms being pulp arteries, sheathed arteries, or pulp arterioles. They were able to see only the peripheral portion of the follicle capillary network, the ultimate twigs penetrating the marginal zone of the red pulp. Terminal capillary branches, as many as eight in number, enter the adjacent red pulp and develop funnel-shaped dilatations. These arteriocapillary ampullae communicate directly with the pulp interstices by way of numerous apertures. As the lumen of the capillary widens in the formation of its ampulla, the refractive quality of the vessel wall is rapidly lost. The parallel linear shadows produced by the capillary are replaced by the contours of pulp cells.

Venous sinuses originate in the red pulp by an enclosure of pulp spaces. A venous sinus gradually increases in diameter to a maximum and then joins a vein. The wall of the venous sinus is composed of loosely connected cells lying parallel to the long axis. The openings between these cells, according to MacKenzie *et al.*, permit the free passage of blood cells.

The interstices of the pulp provide the one and only type of connection seen by them to link the arterial and venous systems in the spleens of mice, rats, rabbits, guinea pigs, and cats. They state, however, that in all spleens there were instances when an arterial capillary appeared to be connected by a vessel to an adjacent venous sinus, but this proved to be an optical illusion caused by weaknesses inherent in the transillumination technique. Spontaneous

arterial vasoconstrictions were seen to occur intermittently and were a factor in the control of circulation of blood through the small vessels as were trabecular and capsular contractions. MacKenzie *et al.* believed that the results of their work supplied additional confirmation of an open circulation for the mammalian spleen.

Bjorkman (11) studied rabbit spleens following the injection of starch granules and concluded from the distribution of the grains that circulation through the spleen was the open type.

A detailed and convincing report in favor of the closed system of circulation appeared in 1951, authored by Peck & Hoerr (94). They selectively attacked statements made in the paper by MacKenzie *et al.* (83), pointing out where possible technical variances could explain the differences in their observations. Peck and Hoerr found the intermediate circulation of the spleen of the mouse to be essentially as Knisely (69) described it. They say that, on arriving at the red pulp, arteries branch two to six times to form the penicillar arteries which then extend into the red pulp 10 to 15 μ before branching several times to form capillaries. Where more than two capillaries arise from a red pulp artery, the termination of the artery may be ampulla-shaped (see fig. 15). There is no discontinuity of the refractile lines from artery to capillary, and these lines caused by the vessel walls must be endothelium or reticular fibers. Capillaries extend in all directions from the ampulla-like terminations of the penicillar arteries to terminate in venous sinuses or venules (fig. 16).

The course taken by a capillary may be straight, curved, or tortuous. If they have a tortuous course it is often difficult to follow them because they run under other vessels or extend beyond the range of focus. Capillaries may turn away from view at their point of origin, giving the ampulla-like termination of the penicillar artery the appearance of ending in a sac or pouring its blood into the pulp. The capillaries can be seen to terminate in the venous sinuses, the walls of which (more difficult to see in the contracted spleen) are continuous with the walls of the capillary.

Penicillar arteries have a powerful sphincter action, although an artery may contract along its entire length. Individual arteries may exhibit this constriction independently of neighboring arteries, which continue to have a rapid flow. Fairly constant blood flow over a period of hours is seen in straight capillaries which terminate in venules. In some cases red cells may seem to wander in the extravascular tissue,

FIG. 15. An ampulla of a red pulp artery.
[From Peck & Hoerr (94).]

FIG. 16. Diagram summarizing the main types of arterio-venous connections in the mouse spleen. [From Peck & Hoerr (94).]

but proper focusing shows them to be within tortuous capillaries.

Peck and Hoerr conclude from their observations that blood in the spleen passes through lined, intact blood vessels which join the arterial and venous systems.

The next major reports on intermediate circulation in the spleen were by Parpart *et al.* (93) and Whipple *et al.* (133), and favored open circulation. These investigators saw three ways in which trabecular arteries, terminating as arterioles, connected with

collecting veins. Most of the arterioles spewed blood through funnel-shaped openings into large pulp spaces from which the blood flowed into collecting veins. Some of the arterioles made direct connection with collecting veins, and such connections were called arteriolar-venous anastomoses. A few of the arterioles were seen to branch into a loose, irregular capillary network which formed venules that returned to the collecting veins. Considering each component of the system from arteriole to veins separately, Parpart *et al.* (93) state the following: Terminal arterioles are thick and muscular and show continuous diameter changes due to constriction and relaxation of the vascular muscle. The terminations of these arterioles are usually three-dimensional and funnel-shaped with the flared ends becoming too thin to be seen with the microscope. This indicates, according to Parpart *et al.*, that the flare thins out to a condition of no endothelial covering of the blood that flows out of the ampulla into the pulp. The pulp space may be fed by only one arteriole or by several. Pulp (reticular) cells are scattered throughout the space seemingly held in position by connective tissue strands. Red and white blood cells can be seen to enter and leave the main stream of blood flowing through the pulp space, remaining outside the stream and thus stationary for variable periods. The pulp spaces are interconnected as shown by the passage of blood cells between them. Collecting veins are seen in the pulp spaces at positions opposite to the arteriole entrance, receiving blood through end and lateral openings in their walls. The lateral openings are large enough in some instances to allow the passage

of several red cells abreast. The collecting veins are described as thin-walled structures randomly perforated with holes of varying sizes that are part of a branched-treelike arrangement. Although capillary networks supplied by an arteriole and feeding into veins are occasionally seen, there are relatively few of them. The capillaries are said to have holes in their walls through which blood enters or leaves the adjacent pulp space.

Parpart *et al.* report that they have never seen a venous sinus of the type described by Knisely (69), nor have they seen any activity in the venous pulp spaces that could be regulatory to the blood flowing through them. This is in direct opposition to statements by Knisely (71) and by Peck & Hoerr (94) regarding the regulation of blood flow through the splenic pulp. Knisely (71) took exception to the conclusions of Parpart *et al.* (93), particularly pointing out that their optical arrangements were such that not all structures present in the tissue would necessarily be observed. With the quartz rod, which Knisely used, it is possible to direct the light first one way and then another and thereby make previously unobserved structures visible (69).

In 1958, Snook (115), who believed one reason for disagreement concerning splenic circulation was the structural variability of the spleen among mammals, reported on fixed rabbit spleens. He had previously classified the mouse with mammals that had non-sinusoidal spleens (114), and comparative studies showed that the rabbit spleen was more nearly like human spleen than the other animals observed. Conclusions from his histological studies of the rabbit were that rabbit spleen had the open type of intermediate circulation, that white pulp capillaries occasionally connected directly with premarginal sinuses, and that penicillar branches terminated in pulp cords in ampullary dilatations.

In the 1958 edition of Bailey's *Textbook of Histology* (112) the authors take the stand that "there is a fairly direct connection from the capillary to the venous sinus in most cases, but the system is open in the sense that the lining membrane changes from endothelial cells to flattened reticular cells, and contains perforations through which erythrocytes may readily pass."

Fleming & Parpart (41) investigated the spleens of young rats and found them to be very different from mice. Capillary networks were seen which had a pattern very similar to that of mesenteric circulation (144). No venous sinus or pulp spaces were found.

Vascular walls were easily seen and very few red blood cells were free in the intercellular space.

Fleming and Parpart suggest that such a capillary pattern in the rat is an infantile characteristic and that pulp spaces develop when the animal becomes more mature. They believe that the fact that endothelial walls can be seen with such clarity in this preparation proves that they could also be seen, if present, in the spleens of mice. Thus the position taken by Parpart for an open system of intermediate circulation in the mouse spleen appears strengthened.

It is very difficult for an unbiased reader to decide in favor of one or the other types of circulation in the spleen because of the convincing arguments presented by the proponents of each. It has been suggested, however, that the burden of proof rests upon those who favor the open type of circulation, since endothelium is universally present in every other vascular system (26).

There are one or two structural arrangements described by Parpart *et al.* which would be unique if they do exist, i.e., capillary vessels with holes in their walls through which blood enters or leaves the adjacent pulp area, and veins which have end and lateral openings varying in size from 5 to 20 μ , the latter openings being randomly spaced along the endothelial lining of the veins.

Williams (139) expressed the opinion that the entire spleen might be thought of as a modified blood vessel with certain special structures in its lumen and, therefore, that the endothelial lining of the internal blood channels might have a different significance than elsewhere.

Microcirculation in the Lung

Microscopic observations of pulmonary circulation date back to Malpighi (84) in 1661. Occasional reports appeared in the literature from time to time after this, possibly the greatest concentration being in the 1930's.

In 1930, Olkon & Joannides (91, 92) studied the pulmonary circulation in dogs, frogs, and alligators! The optical magnification was quite low by present day standards (60 \times) and the fact that the animals were on artificial respiration and their lungs in constant motion must have added considerable difficulty to their investigation. They describe what appeared to be a large capillary lying between the walls of the alveoli from which many smaller capillaries were given off. They believed that the single large capillary surrounding the alveolus was most likely a capillary

FIG. 17. Sketch of air sac and its vessels in the lung of a cat. [From Wearn *et al.* (128).]

network seen on edge. The smaller capillaries anastomosed frequently with each other and appeared to contract and relax.

In 1933, Daly (38) reviewed pulmonary circulation and briefly mentioned microscopic observations of pulmonary vessels, but these studies were concerned primarily with the response of small vessels to epinephrine. There were no papers in which normal vascular patterns were described.

Wearn *et al.* (128) introduced a method for the observation of minute vessels in the lung which utilized a quartz rod, for transmitting light, placed inside the chest cavity. The vessels were observed microscopically in the lung tip through a window in the chest wall. Observations were made on both moving and immobilized lungs. Arteriolar vessels showed pulsatile flow and steady flow, a different type of flow often occurring in two arteriolar branches from the same parent arteriole. Arterioles were seen to contract and relax, and reversal of the direction of blood flow was common. The walls of the capillaries were invisible, so that the caliber of the vessel and its course were determined by the column of blood it contained. Capillary vessels were seen to branch and anastomose frequently (see fig. 17). Wearn *et al.* report spontaneous opening and closing of capillaries, but the fact that the differentiation between arteriole and capillary was based on the number of blood cells which the vessel would accommodate (three or less for a capillary) throws some doubt on the validity of this statement. Also, the suggestion is made later in the report that intermittent flow in capillaries was

probably due to changes in the flow of arterioles from which the capillaries arose and that no proof of contraction of capillary walls was obtained. The capillary network, depicted by Wearn *et al.* as covering an alveolus, is very similar to that in many other sites.

The next detailed report of vascular architecture of the lungs appeared in 1954, when Irwin and his associates (66) published the results of microscopic observations on guinea pigs and rabbits. The technique used was that of transillumination with a quartz rod and oxygen insufflation to prevent respiratory movements. These investigators traced pulmonary arterioles to terminal pulmonary arterioles which branched to form capillaries. Blunt terminations of pulmonary arterioles, which lie in the septa between alveoli, gave rise to capillaries which then spread over several adjacent alveoli. Pulmonary capillaries were seen to be completely lined cylindrical tubes which branched and anastomosed to form intricate networks over the surfaces of alveoli. The capillary network was often supplied by several terminal arterioles and each network was drained by more than one venule. Arteriovenous shunts were found between a pulmonary arteriole and venule that ran side by side in an alveolar septum.

Additional observations by Irwin & Burrage (67) were that the diameters of arterioles and venules changed size when measurements of their walls were made over long periods of time, affecting the flow of blood. Alterations in the diameters of the arterioles were more marked than venular changes. Irwin and Burrage report that the walls of the capillaries covering an alveolus were seen to come together to obliterate their lumina. They suggest that, although the intermittent blood flow in pulmonary capillaries could be due to contraction of either arterioles or venules, the possibility of activity in the capillary walls must be considered. That capillary walls might contain contractile tissue, or that the endothelium lining the cells might swell to block the lumina are the possible means offered by the authors for causing intermittent flow in pulmonary capillaries.

A surprisingly small number of investigations of the normal vascular structures and flow of blood in microscopic pulmonary vessels have been carried out. However, Wearn's, diagrams (128) and the descriptions by Irwin *et al.* (66) of capillary networks covering alveoli indicate that this terminal vascular bed is made up of the same structural components with the same basic form as that of beds in other tissues and organs. Perhaps further investigations will explain the apparent closure of "capillary" walls seen by Irwin &

Burrage (67). The most likely explanation for intermittent flow through these minute capillary vessels is that the terminal arterioles and precapillary vessels which supply the capillary nets exhibit spontaneous vasomotion as seen in other areas.

Microcirculation in the Cochlea

The general pattern of blood vessels of the cochlea has been known for some time, the early descriptions being obtained from injected and fixed material. In general terms (40) the cochlea is supplied by the cochlear artery. This vessel enters the modiolus through the internal auditory meatus. The spiral ganglion has a rich supply of capillaries, and many arterioles find their way to the spiral ligament by way of the roof of the scala vestibuli. The stria vascularis is a rich network of small blood vessels with many anastomotic connections. The limbus has a capillary supply, and the tympanic surface of the basilar membrane often has a small arteriole running along it. Renewed interest in the blood supply of the cochlea in the past few years has resulted from applying microcirculatory techniques to this rather inaccessible site.

The capillary networks of several portions of the cochlea have been studied in detail. The areas so studied include the spiral ligament, a projection of thickened periosteum lying on the outer wall of the osseous canal of the cochlea; the spiral prominence, a slight ridge which projects into the cochlear duct; and the stria vascularis, the part of the spiral ligament lying on the outer wall of the cochlear duct between the spiral prominence and the vestibular membrane.

Two papers by Smith (110, 111), which contain a

detailed description of cochlea blood vessels obtained from fixed material, will be considered before discussing *in vivo* preparations. Investigations of capillary beds following intravascular precipitation of Prussian blue or lead chromate in the cochlea of guinea pigs, cats, and humans were carried out by Smith. She felt that while large features of the circulatory patterns had been adequately demonstrated, the capillary beds had been indistinctly shown and no attempts had been made to locate them precisely in relation to various portions of the inner ear.

In these studies, the radiating arteriole was found to ramify into terminal branches before entering the spiral ligament. In the cat and guinea pig four groups of small vessels, depending on their location and the course which they took, were designated by Smith. The first group was the network of the upper spiral ligament, group two was in the stria vascularis, group three was found in the spiral prominence, while group four was formed by the capillaries of the lower portion of the spiral ligament. In human labyrinths a fifth group, straight vessels in the thicker portion of the spiral ligament, was included in the classification (see fig. 18). The network in the upper spiral ligament is described as follows: Small branches from the radiating arteriole or one of its terminal ramifications have a winding course in a spiral direction usually above the attachment of Reissner's membrane. These small branches are seen to anastomose with other tributaries. They leave the upper spiral ligament by turning downward to the thicker part of the spiral ligament where they join venules, or they may turn upward and go through the bone wall to end in a collecting vein. The capillaries in the second group, the stria vascularis, are extensively connected with

FIG. 18. Schematic drawing showing typical distribution of small blood vessels in the spiral ligament of the human cochlea. [From Smith & Giovacchine (113).]

one another and give the appearance of a network superimposed upon the deeper vessels of the spiral ligament. The superior and inferior borders appear straight and parallel. A large venule drains the network, formed by the junction of three or four stria capillaries. The venule turns backward and leaves the stria vascularis in its lower half where it descends peripherally, sometimes joined by other venules before entering into the collecting venous system at the lower edge of the spiral ligament. The blood supply of the spiral prominence, the third group, is different in the guinea pig from cat and man. In the guinea pig a single vessel is found near the epithelial layer, with perhaps a single layer of connective tissue cells interposed. The vessel courses parallel to the network of the stria vascularis just below its inferior border, although no vessel of the spiral prominence is ever connected to the network of the stria vascularis. At times the vessel is double, with the duplicate vessel running under the edge of the stria vascularis. The venules join the collecting venules of the lower spiral ligament. In the human, the vessels in the spiral prominence form a separate, narrow, rolled network below the stria vascularis, supplied by large arteriolar vessels and drained by large veins. Small vessels leave the network by turning upward and laterally into the spiral ligament before emptying into veins. They also may enter venules in the lower spiral ligament.

The capillary network in the lower spiral ligament is also supplied by direct large arteriolar branches. These arteriolar branches descend close behind the stria vascularis and terminate in a spiral vessel in the crest of the spiral ligament. Branches are given off to the stria vascularis and spiral prominence on the way. The spiral vessel marks the upper limit of a network which originates from it. Where the spiral ligament is quite thin, the network can be seen as a loose mesh of vessels under the mesothelium of the scala tympani.

The fifth group found in the human is made up of straight vessels found in the connective tissue between the scalae and the bone. They show variations in size and structure, and course directly from arteriole to venule. Some seem to be capillaries, being devoid of perivascular cells, while others are larger and may represent a type of arteriovenous shunt.

The radiating arteriole was found to have both longitudinal and tangential smooth muscle cells and a thin adventitia of two or three layers of connective tissue cells. Capillaries were composed of endothelial cells and infrequent smooth muscle cells. The capil-

laries of the stria vascularis were composed only of endothelial cells, although occasionally a perivascular cell was seen. It could not be determined whether it was a smooth muscle cell or not. The large draining vein was seen to have a few smooth muscle cells arranged transversely or tangentially.

Smith concludes that the human cochlea shows a definite arteriolar supply to the various vascular groups of the spiral ligament. There are several distinct capillary networks rather than one large continuous field, and these networks are separated by their vascular supply and drainage. She suggests that such a vascular pattern makes it possible to have regional circulatory variations within a small segment of the spiral ligament.

In 1954, Weille *et al.* (131, 132) published two papers describing the circulation in the spiral ligament and stria vascularis of the living guinea pig. The cochlea was first exposed and then microscopic fenestration of either the apical or third cochlear turn was carried out. The vessels observed included arterioles, arteriovenous anastomoses, capillaries, and venules of the spiral ligament and the capillary network of the stria vascularis. Capillaries of the spiral ligament formed an intricate network of dividing and anastomosing vessels fed by arterioles. Arteriovenous anastomoses were formed as a branch of an arteriole that entered a venule with no intervening capillary network. The capillaries of the stria vascularis formed a network of branching and anastomosing vessels that emptied into the venules of the spiral ligament.

All arterioles, arteriovenous anastomoses, and venules contracted and dilated independently. The rate of blood flow varied in each vessel from time to time, going from very rapid to no flow at all.

A more detailed description followed (65), in which it was reported that there were two distinct types of tiny vessels, one in the area of the upper spiral ligament and the other in the area of the pigmented cells (the cochlear duct). Branching and anastomosing were frequent in these networks. Both received blood from the arterioles and both drained into the venules in the area of the cochlear duct.

Collecting venules, into which the capillaries drain, pass transversely through the area of the cochlear duct, and drain into the venules which are perpendicular to them and lie outside this area.

Vessels which ran from arterioles to venules were seen to give off capillaries, but no capillaries were seen to re-enter them. For this reason they were called arteriovenous anastomoses rather than met-

arterioles, a name given to them by Seymour (109). The anastomoses were seen to contract to complete closure.

Microscopic observations of cochlear blood vessels in living guinea pigs were reported by Perlman & Kimura (95, 96) in 1955. Special attention was given to the small vessels of the spiral ligament and the stria vascularis. The quartz rod technique was used after the cochlea was fenestrated in the fourth turn. The fenestra was 0.1 to 0.2 mm² and exposed the spiral ligament on the lateral wall of the cochlear duct as well as the stria vascularis. Perlman and Kimura were certain that all vessels in the field were visible to them and that all the basic units of a vascular bed were present. The identification of the various components was based on the diameter, the wall thickness, shape of the vessels, the rate and direction of flow, and the presence of smooth muscle cells and vasomotion. Numerous anastomoses between all types of vessels were seen, but the distribution and direction of flow from the radiating arteriole to the collecting venule suggested a segmental blood supply.

The arterioles of the spiral ligament were seen to branch into a number of different vessels. A small branch at right angles to the radiating arteriole was seen to run parallel to the cochlear duct in the upper portion of the spiral ligament. It anastomosed with a similar vessel from an adjacent arteriole.

Another branch was seen that crossed the underlying stria vascularis and emptied into the collecting vein below the cochlear duct. This type of vessel, regularly seen in the area, has no branches, is narrow and straight, and has a rapid blood flow. It has

smooth muscle cells regularly distributed along its walls. The authors have called this vessel an arteriovenous arcade. (See figs. 19 and 20.)

Another branch of the radiating arteriole with a uniform diameter extends over the underlying stria vascularis, has no branches, and ends at the level of the spiral prominence just below the stria vascularis. The vessel with which the branch connects runs parallel to cochlear duct and tributaries from it join collecting venules of the spiral ligament. The blood vessels in the stria vascularis are at right angles to the radiating arteriole, the collecting veins, and the arteriovenous arcade.

The last branch from the radiating arteriole is the one which enters the stria vascularis. Diameters of the stria vessels are usually larger than the diameters of the radiating arteriole or arteriovenous arcades. Stria vessels do not have a regular distribution of smooth muscle cells and were not seen to contract.

The vessel in the spiral prominence is independent of the stria vascularis, being directly supplied by a branch from the radiating arteriole. A large number of tributaries leave this vessel to join the collecting vein. Anatomically, it seems to have the qualifications of a capillary, being small in size and devoid of smooth muscle cells, and having a slow rate of blood flow. It shows no vasomotion.

In commenting on the vascular pattern, Perlman and Kimura state that the segmental type of blood flow suggests that interference with function may be localized. Interruption of flow in a radiating arteriole of an arteriovenous arcade may occur while flow continues in the underlying stria vascularis. Flow in the stria vascularis may cease while active flow continues in the radiating arteriole, arteriovenous arcade, spiral prominence vessels, and venules. The presence of arteriovenous arcades in the spiral ligament suggests a possible regulatory mechanism for controlling flow in the stria as well as affording anastomotic channels to insure continuity in blood flow along the spiral ligament.

Perlman believes that the stria vessels, the arteriovenous arcade, and the spiral prominence vessels have functional roles. The stria vessels may be called capillaries with regard to their position, the fact that they have the lowest blood flow rate, and the fact that they have no smooth muscle cells in their walls. The decrease in the rate of blood flow from the radiating arteriole to these capillaries of the stria vascularis is large and abrupt. The final exchange of diffusible substances probably occurs in these vessels.

The role of the cochlear blood vessels in the absorp-

FIG. 19. Segment of cochlea showing relation of exposed vessels to the cochlear duct and the main trunks in the modiolus. [From Perlman & Kimura (95).]

FIG. 20. Schematic drawing showing relations of basic vascular units exposed by the fenestra and the average blood velocity in micra per sec. [From Perlman & Kimura (95).]

tion and secretion of perilymph and endolymph is still not clear, although it is believed that endolymph is secreted by the stria vascularis (40). It is interesting that this fluid, which fills the scala media, differs in ionic content from perilymph which fills the scala vestibuli and the scala tympani. Unlike all other extracellular fluids in the body, endolymph is high in potassium and low in sodium, thus more nearly resembling an intracellular fluid. The very slow rate of blood flow in the stria vascularis may be necessary to allow the formation of this intracellular-like fluid.

It has been suggested, also, that the slow flow rate and the absence of vasomotion in the stria vessels contribute to the fact that blood flowing through the cochlea is not heard.

Preferential or Thoroughfare Channel

The attempt to give a representative description of vascular patterns in terminal vascular beds has not escaped the usual criticisms aimed at generalization from one animal to another or among different tissues within the same animal. One of the major issues among investigators of the microcirculation has been the acceptance of a preferential channel as a component of all capillary networks. A chronological presentation of the development of the concept, the modifications, and current status might assist in clarifying the issue.

The first description of the arteriovenous (a-v) bridge, later to be called the thoroughfare or preferential channel, appeared in 1937 (143). Zweifach, in studies of the mesentery, nictitating membrane,

and undersurface of the tongue of the frog, described two types of vessels present in these structures. One was a continuous central trunk that connected an arteriole and a venule. This vessel, a direct continuation of an arteriole, was invested with widely separated atypical smooth muscle cells which were less responsive to mechanical stimulation than smooth muscle cells of the arterioles. The a-v bridges did not always take a direct linear course from the arterial to the venous side, but appeared in three basic patterns: 1) a direct course without other terminal branches, 2) a fountain-shaped pattern, 3) a horse-shoe-shaped pattern, which was to become regarded as the basic design for the preferential channel. The a-v bridge was functionally different in that it always had a patent lumen with uninterrupted blood flow. The second type of vessel was the true capillary, a nonmuscular vessel which was an off-shoot or branch from the a-v bridge, not in the direct path of blood flow from arteriole to venule. In a camera-lucida drawing of the vascular pattern in the frog mesentery it can be seen that the a-v bridge either formed a loop to return to the venule accompanying the arteriole from which it arose, or continued across the capillary bed to join another venule (fig. 21).

In a second paper the same year, the arteriovenous bridge was reported in the mesentery and ear of the mouse (150). In 1939, Zweifach (144) extended his studies on living vessels in the mesentery, tongue, skin, and intestinal wall of the frog, and in the mesentery and ear of the mouse. Little new information was added, but the functional significance of the a-v bridge was stressed. The main central pathways were

FIG. 21. Camera-lucida outline of vessels in the capillary bed of the frog mesentery. [From Zweifach (143).]

said to have a vigorous circulation even when tissues were in a resting or anemic state. The bridge was regarded as a muscular capillary and was the central pathway from which the remainder of the capillary vessels were distributed as side channels.

In 1944, Chambers & Zweifach (20) collaborated on a paper in which the studies were confined to the mesenteric circulation in the dog and the rat. They state that the fundamental architecture is the same for both tissues. The mesoappendix of the rat differs from other parts of the mesentery in its lack of any major vessels coursing from the aorta or to the vena cava, all vessels in the mesoappendix being less than 80 to 100 μ in diameter. The description of the capillary bed is based primarily on observations in the mesoappendix of the rat, in which the a-v bridge is a prominent structure. The term "metarteriole" (Gr. meta—beyond) is introduced to designate the proximal contractile portion of the central channel. Beyond the metarteriole, muscle cells disappear and the channel continues as the a-v capillary until it joins a venule. Other contractile muscle cells, designated precapillary sphincters (the precursors of the true capillary), were found at the proximal end of the channel but were absent at the venular end. Each central channel and its side branches with their interposed true capillaries were said to constitute a structural unit. In a summary in 1946, Chambers & Zweifach (21) state that the basic topography of a predominantly nutritive type of capillary bed is presented as a central channel of which the true capillaries are side branches. The different portions of the central channel, in sequence, were the metarteriole which exhibits vasomotion and has typical but discontinuous muscle cells; the proximal portion with atypical muscle cells; the distal portion with no muscle cells; and the nonmuscular venule. The precapillaries were described as the proximal muscular portions of the abrupt offshoots of the muscular portion of the central channel, acting as sphincters and

controlling blood flow through capillaries. The true capillaries continue from the precapillaries and are also direct branches of the distal portion of the central channel and of the nonmuscular venule.

In 1947, the functional aspect of the structural unit was again emphasized (22). It was pointed out that in some tissues which maintain a constant level of flow volume there is no discernible organization of capillaries, while in tissues such as the muscular system and the gastrointestinal tract with varying activity the structural unit exists. This vascular pattern allows for great expansion in the number of vessels with an active circulation at one time and restriction of flow to the preferential channel during a period of inactivity. In the decade following the introduction of the preferential channel, new ideas and new terminology were added. For clarification of the structure and function of the terminal vascular bed in the rat mesentery, excerpts from a paper by Chambers & Zweifach (22) follow. "The preferential vessels have been termed thoroughfare or a-v channels. The proximal portion of these channels, termed metarterioles, together with their precapillary sphincteric offshoots, are muscular and spontaneously undergo periodic changes in caliber. This type of movement has been termed vasomotion, a slow intermittency of partial relaxation and constriction at intervals of about 30 seconds to 3 minutes. . . . The precapillary sphincteric offshoots lead into an interanastomosing system of true capillaries (devoid of muscle elements) which constitutes the bulk of the bed. The capillaries rejoin the distal continuation of the thoroughfare channels through inflowing tributaries." The thoroughfare channels, always open, are said to maintain a constant pressure relationship between their arteriolar and venous ends, the flow of blood through them being more rapid than through other vessels in the bed. The channel is said to be the site of outward filtration, while inward filtration occurs in the true capillaries.

One significant anatomical difference noticed in comparing microphotographs of circulatory patterns in the rat mesoappendix with that of other tissues is the absence of paired arteriole and venule in the mesoappendix of the rat. An arteriole emerges singly from its parent vessel, descends into the mesentery, then forms a loop which in its return is joined by other capillary vessels before emptying into the vein which accompanies the artery of origin. In most vascular beds, other than the mesentery, arterioles and venules are found to be adjacent and to branch together until the final ramification which forms the capillary net. The small arterioles, from which the true capillaries arise, form arcades or arcuate patterns with other arterioles rather than continuing as a direct pathway to the venous side. It is not uncommon to see, in the bat wing at least, a short terminal arteriole that quickly joins a collecting venule after giving off one or two branches (see fig. 22). Contrary to the description given to preferential channels these terminal arterioles will close down completely or may be devoid of blood when their parent vessel is occluded by contraction of the circular smooth muscle which invests them.

According to subsequent papers by Zweifach (146, 147) and Zweifach & Metz (151, 152), in which vascular patterns are compared, it seems that the preferential channel occurs mainly in rat mesentery, outer edge of rat skeletal muscle, and the serosa of the small intestine of the same animal. He states that the preferential channel is unusually prominent in the mesentery but is not a major structural feature of the urinary bladder and the skin. Further reservations as to the ubiquitousness of the preferential channel have appeared as a result of observations in the under surface of the skin, the skeletal muscle, urinary bladder, several mesenteric structures, and the serosal surface of the small intestine. Zweifach states that "a major variable lies in the structural organization of

FIG. 22. Arteriovenous pathways in the subcutaneous area of the bat wing.

the different vascular beds, especially the mode of distribution of the capillary system from the arterial vessels. In such tissues as skin and intestinal wall, the majority of capillaries originate as direct offshoots of larger arteries and arterioles. The distal ramifications of the arterioles have relatively few capillary offshoots and usually terminate by interconnecting freely with one another in a series of arcades. This is in direct contrast to the mesentery where the arterial subdivisions, the metarterioles, serve as the parent stem from which the precapillaries and capillaries branch out."

Other investigators who have found thoroughfare channels in various tissues include Lutz *et al.* (82), who confirmed their presence in frog mesentery but failed to identify them in the hamster cheek pouch or retro-lingual membrane of the frog. Baez (6) reports a short arteriole which turns inward to become a draining venule, thus forming a thoroughfare channel in the muscular coat of the small intestine. Staple & Copley (118) describe a thoroughfare channel in the labial marginal gingiva of the mandibular incisor of the hamster. Lee & Holze (77) observed the thoroughfare channel in the human conjunctivae, and Lee & Lee (78) describe the structure in the mesentery of the guinea pig.

The preferential or thoroughfare channel, either as a structural or functional unit, has not been seen in some areas which have been subjected to extensive study by various microcirculatory investigators. Nicoll & Webb (88) report that there are no preferential pathways in the subcutaneous tissues of the bat's wing. Clark & Clark (29) do not report them in the rabbit ear. Grafflin & Bagley (55) found no such structure in the frog web and urinary bladder, nor in the human conjunctivae. Later, Grafflin & Corddry (56), reporting a more detailed study on the bulbar conjunctiva of man, described vessels between arterial and venous channels, arteriovenous communications that seem similar to the preferential channel.

It would seem then that the preferential channel should not be considered as a component of a typical capillary network. Although it is possible to demonstrate a similar anatomical arrangement in terminal vascular beds other than in the mesentery, there is no confirmation of the existence of a preferential channel on a functional basis. It is possible that such a flow pattern is necessary for the relatively avascular mesentery, and therefore constitutes a special rather than a typical entity of microcirculation.

Arteriovenous Anastomoses

A detailed and comprehensive review by Clark (23) in 1938, dealing with arteriovenous anastomoses, obviates the necessity of reporting individual investigations up to that time. The discussion here is mostly confined to the results of *in vivo* studies.

A direct connection between arteries and veins by passages through which blood is carried without interchange with extravascular fluids had been described repeatedly since the early 1800's. Such passages were then considered to be rare, occurring as a result of injury or as a developmental anomaly. Their presence in the ear of the living rabbit, as demonstrated by Clark & Clark (29, 30) and Grant (57), established their existence in the normal vascular bed.

Grant (57) concluded from his observations of reactions of these vessels that arteriovenous anastomoses were important in regulating body temperature. Responses to heating the animal indicated that when the body temperature was elevated, dilation of arteriovenous anastomoses permitted a large amount of blood to flow through the ear, thereby increasing heat loss. Constriction of arteriovenous anastomoses occurred when the animal was cooled and thus heat was conserved. This concept was extended in studies of the toes of birds and the fingers and toes of man (58).

Clark & Clark (30) studied the arteriovenous anastomoses in transparent chambers in the rabbit ear with observations over long periods at high magnifications. High magnifications made possible the descriptions of structural components. Many arteriovenous anastomoses are present in the ear of the rabbit, with considerable variations in their arrangement. Some arise directly from the central artery of the ear, others from secondary or smaller branches, and some form the termination of an artery or arteriole. Most of these, however, arise from small arterial branches. They all empty primarily into larger veins (see fig. 23).

As to the structure, arteriovenous anastomoses are found to be straight or coiled, with a thick muscular wall on the arterial side and a thinner, funnel-shaped widening on the nonmuscular venous end. Variations from this general pattern include the absence of the funnel-shaped venous end and a continuous muscular wall throughout the entire vessel. The narrow intermediate portion has a wall of extra thickness which seems to be the most contractile portion. The venous portion is noncontractile, but the large veins with which the communicating vessel connects often have substantial muscle walls and show definite contrac-

FIG. 23. Camera-lucida drawing of a plexus of regenerated vessels in the rabbit ear. [From Clark & Clark (34).]

tility. Most of the cross connections show inside diameters of 20 to 40 μ during dilatation. Typical anastomoses may be as small as 5 μ in diameter or as large as 40 μ .

Arteriovenous anastomoses are more active than arteries and arterioles and show a greater tendency for independent action. They contract and dilate spontaneously and periodically, but with a rhythm independent of either neighboring anastomoses or even of the artery from which they arose. They generally contract more rapidly than arteries, both rhythmically and in response to stimuli.

Clark (23), did not attempt to explain the function of the arteriovenous anastomoses, but felt that it was significant that they occur normally in greatest numbers at sites most frequently subjected to mechanical and thermal irritations, the kinds of stimuli which produce prolonged dilation of arteries and arterioles.

From his observations of the frog mesentery, Zweifach (143) describes short arteriolar-venular anastomoses between vessels only slightly larger than capillaries. These short channels effectively divert arterial blood directly into veins. Their caliber changes seem related to the activity of the capillary circulation. When most capillary vessels are open and have active blood flow, the arteriolar-venular anastomoses remain closed, and then open when capillary circulation decreases. The anastomoses differ in this respect from arteriovenous bridges which maintain a relatively fixed diameter. Arteriolar-venous anastomoses in the mesentery of the mouse were described as short, tor-

tuous vessels that never branched and were not part of the capillary bed.

Later, similar vessels in the rat mesoappendix were described (20). The connecting passages in that tissue join a metarteriole with a neighboring venule, or an arteriole with a venule. They are muscular for about two-thirds of their length from the arterial end. When such shunts dilate, blood flow ceases in the arterial components distal to the shunts.

Direct microscopic observations in other tissues of living animals have revealed arteriovenous anastomoses. Wakim & Mann (124) carried out microscopic studies on the liver of frogs and various mammals at magnifications up to 600 times, utilizing the quartz rod transillumination technique. They found arteriovenous anastomoses in all animals studied. They saw anastomotic connections between the interlobular branches of the hepatic artery and the portal vein in both amphibian and mammalian livers. Seneviratne (108) observed blood vessels of the livers of frogs, mice, and rats, and described similar anastomoses. For frog liver he described several phenomena. Many short branches from a hepatic artery enter the accompanying portal vein. Arterioles cross a lobule and enter a portal vein on the other side. Occasionally the arteriole enters a hepatic vein. Small arterial branches pass through the liver and anastomose with subcapsular arteries. In the mouse and rat many types of anastomoses occur between arterial and venous vessels, the commonest being a direct communication by short branches between the hepatic artery and the accompanying portal vein.

Irwin & MacDonald (64) studied guinea pig livers using the quartz rod technique and found the vascular bed to be similar to that described for the liver by Knisely *et al.* (72). The Knisely group found connections between hepatic arterioles and portal venules which they called arteriportal anastomoses. Bloch (14) described arteriportal anastomoses (APA) as being completely lined smooth-walled tubes that connect hepatic arterioles with portal venules at irregular intervals. The hepatic arteriole winds itself around the portal venule and then sends short branches out to form APA.

Parpart *et al.* (93) describe arteriovenous anastomoses in the spleen of the mouse as seen by microscopic observation. There, about one artery in ten makes direct connection with a collecting vein. An arteriole may anastomose with a collecting vein at any point on the vein, lateral connections occurring more frequently than end-to-end anastomoses. When the connection is lateral, the arteriole is perpendicular

to the venous wall. In the end-to-end anastomosis, the arteriole gradually widens to become a collecting vein.

Poor & Lutz (97) found no arteriovenous anastomoses in the hamster cheek pouch. Irwin *et al.* (66) found arteriovenous shunts in the lungs of guinea pigs and rabbits, although they appeared infrequently. Blood flow through the shunts was unidirectional, going from arteriole to venule. Blood flow through arteriovenous anastomoses in the bulbar conjunctiva has been described by Bloch (15). Weille *et al.* (132) saw them in the stria vascularis.

Zweifach (148) has said that there is little doubt that occasional shunts between arteries and veins exist in almost every tissue in the body, but are not a prominent feature of most tissues. He further suggests that pathways, not distinct anatomical shunts, go from arterial to venous systems allowing blood to bypass the capillary network. Communications between arterial and venous vessels occur more frequently in terminal vascular beds than in more proximal portions.

It does not seem necessary to assign any highly specialized function to arteriovenous anastomoses, such as heat regulation, although this is still done (39, 98). Folkow (44) is of the firm opinion that arteriovenous anastomoses in the skin are specialized structures predominantly engaged in regulation of heat loss and are regulated by their own constrictor fibers. His evidence, while convincing, is indirect. Van Dobben-Broekema & Dirken (121, 122), in a study of the reaction of rabbit ear vessels to heating, offer evidence that there is no obvious relationship between the temperature of the ear and the diameter of the arteriovenous anastomoses. Zweifach (148) mentions the possibility that selective vasoconstriction may reduce capillary circulation and cause blood to be shunted through passages which would offer the least resistance to flow from the arterial to the venous side.

The information derived from the above investigations indicates that terminal vascular beds of most tissues are supplied with short communicating vessels between arterial and venous systems. These arteriovenous connections allow arterial blood to be shunted into the venous system without first passing through a capillary network. As Zweifach (148) has suggested, the shunts may be preferentially in use when vasoconstriction of small arterial vessels beyond the shunts increases resistance to flow. Arterial blood would then be diverted through shunts which afford the path of least resistance. The selective vasoconstriction to which Zweifach refers might result from the response of terminal arterioles or precapillary sphincters to

changes in the local environment, and thus whether or not blood flowed through capillary networks would be determined by the immediate needs of the tissue. Thus, no complex central nervous control is necessary, if the postulate that terminal vasculature is primarily under the control of local conditions is acceptable.

BLOOD FLOW THROUGH TERMINAL VASCULAR BEDS

Capillary Contractility

Ideas regarding contractility of capillary vessels have come full circle, beginning and ending with the concept that capillaries are noncontractile and the blood flow through them depends on contraction or dilatation of the arterioles which supply them. During the intervening periods, investigators have promoted the concept of independent contractility of capillary vessels, first believed to be brought about by the contraction of perivascular or Rouget cells and later thought to be due to the contraction of endothelial cells. At present it is generally accepted that true capillaries do not contract. By definition they are devoid of muscular elements, so that muscular contractility is out of the question, and the endothelial cells of which they are composed are also noncontractile. The internal diameter of capillaries may vary, however, by passive response to changes in pressure or in the size of the endothelial cells which form the basic structure of their walls.

Independent contractility of capillaries was a controversial subject in the eighteenth century. The opinion expressed by Haller (60) in 1756 that capillaries did not contract was generally accepted by most physiologists until early in the twentieth century [(54), see also (87)]. At this time publications by August Krogh (73) appeared. Krogh's belief that capillaries really contracted is found in a description of an experiment in his book "which demonstrates in a crucial manner that the whole length of a capillary from an arteriole to a venule can be contractile, that it cannot, when contracted, be forced open by the available arterial pressure. . . ." Krogh was convinced of the independent contractility of capillaries but he also believed that no evidence obtained thus far was conclusive enough to explain the mechanism by which this was carried out.

Two possible means of decreasing the diameter of capillary vessels had been suggested. One was that either osmosis, or imbibition by endothelial cells, was

responsible, and the other was that active contraction of extraendothelial cells occurred, as described by Rouget (103) in 1873. Krogh believed that the imbibition theory was ruled out by data published by Steinach & Kahn (119), showing that the outside diameter of contracting vessels decreased, rather than remaining constant or increasing as it would if the endothelial cells enlarged. He believed that anatomical proof was lacking to establish the functional role of Rouget's cell. Because of this need for more histological information, he encouraged Vimtrup to conduct a detailed study of the structure of the capillary wall. Vimtrup (123) examined stained sections of frog tongue and found cells such as those described by Rouget. He subsequently named them Rouget cells. He was also successful in identifying these cells on living minute vessels in the tail of newt larvae, and in seeing them contract. The frequent spontaneous contractions and dilatations of vessels seemed to occur at the location of the nucleus of a Rouget cell. This was final proof for Krogh that capillaries possessed independent contractility, the contractile element being the Rouget cell. He explained away the conclusions of the Clarks (27, 28) that the Rouget cells were noncontractile by saying that there was no proof that the cells they described on vessels in tadpole tails were the same as Rouget cells or that the contractions they saw were similar to normal contractility. Krogh, convinced that the controversy regarding capillary contractility was settled, extended his belief in the Rouget cell to include its occurrence on all capillaries in both Amphibia and mammals.

In a very short time, however, the concept of the Rouget cell as a contractile cell controlling the diameter of capillary vessels was challenged by detailed studies on small vessels in the rabbit ear, a technique introduced by Sandison (104) in 1924, and used by him and the Clarks, in whose laboratory he began his work. A chamber for the rabbit ear was perfected in which original vessels as well as newly formed ones could be watched for many months. In 1931, Sandison (105) reported that the appearance of Rouget or adventitial cells on newly formed vessels occurred in a few hours. Using a magnification of 400 times he could find a clear space between these cells and the vessel wall or an endothelial nucleus. The cells did not remain fixed, but wandered along the vessel wall. Sandison stated that the function of the Rouget cell was obscure, except that it helped form a supporting framework for the vessels. He was able to demonstrate in the rabbit ear vessels that a widening of the space between the adventitial cell and the arteriolar wall

occurred when the arteriole narrowed. Clark & Clark (27) had previously made a similar observation in Amphibia, and also had observed that the contraction of small vessels on which no adventitial cells developed was the same as those in which adventitial cells were present. These observations seemed to rule out any possibility that the adventitial or Rouget cell was responsible for contraction. Sandison also noticed that, as newly formed vessels changed from capillary to arterial forms, the adventitial cells disappeared and circular smooth muscle cells took their place. It was shown later by Clark & Clark (33) that adventitial cells actually differentiated into smooth muscle cells as new capillaries developed into arterioles.

A year later Sandison (106) stated that it was clear from continuous microscopic observation of minute vessels that contraction and relaxation of smooth muscle cells of arteries and arterioles were responsible for alterations in blood flow through capillaries, and that neither Rouget cells nor endothelial cells played any part in contraction of vessels.

In the same year, Clark & Clark (29), after observing capillaries of normal ear tissue through a transparent chamber, stated that if any capillary contractility did occur it was too negligible to have any influence on the circulation. In subsequent papers Clark & Clark (33, 34) summarized the accepted ideas regarding capillary and endothelial contractility as follows: *a)* Studies on mammalian vessels in transparent chambers, where details of the cellular structures could be clearly seen in unanesthetized animals, gave no evidence for any contractile power of either endothelial or adventitial cells. This view was supported by other investigators (61, 101, 102). *b)* The real factors responsible for the control of circulation in the minute vessels of the mammal are smooth muscle cells on arteries, arteriovenous anastomoses, and large veins (105). *c)* No contractile activity is seen in mammalian capillary endothelium (29, 31, 33, 86), although definite active spontaneous contractions occur in the capillary endothelium of Amphibia (28, 142, 143). They point out that the experimental evidence for contractility of mammalian capillaries was based, in some instances, on studies of nontransparent regions in which the structure of the wall of the minute vessels and their true diameters could not be seen. Therefore, conclusions as to whether they were contracted or dilated could only be inferred from the number of red cells present in them. Also, belief in contraction of mammalian capillaries was often based on observations of amphibian vessels in which contractions had

been seen to occur with and without extra-endothelial cells.

In spite of overwhelming contrary evidence, some investigators still held for a time to their belief in capillary contractility. It seems unnecessary to review the disagreements in the face of the general acceptance at the present time of the opinions originally expressed by Sandison (106) and extended by Clark & Clark (29). If one accepts the definition of a capillary as a nonmuscular endothelial tube between the arterial and venular systems, one may state unequivocally that mammalian capillaries are noncontractile.

Nicoll & Webb (88) stated that observations on capillaries in the bat wing showed that no perivascular cells, such as Rouget cells, existed in the region of these vessels. The smooth muscle cells, at the transitional points from the terminal arteriole to the capillary, end rather abruptly. Beyond the termination of smooth muscle cells within the walls no change in the diameter of the capillaries, due to activity of perivascular cells, has been observed.

The question of the role played by the endothelial cell in caliber changes in capillaries is more unsettled. To cite some of the recent descriptions of endothelial cell activity, Nicoll & Webb (88) reported modifications in capillary diameter that may result from elastic recoil of the endothelial wall due to pressure variations either inside or outside the vessel. The caliber change is due neither to active contraction of the endothelium nor to intracellular swelling. Later, Webb & Nicoll (130) pointed out that loss or gain of fluid through the walls of endothelial cells may result in apparent changes in their size. Also, since capillaries are distensible, they may show deformation under variable conditions (89). These responses are usually slow in their development and give no indication of active participation by the endothelial cells. Chambers & Zweifach (21) believe that slow spontaneous endothelial responses for the most part represent accommodation to changes in pressure; that endothelial cells possess a cellular tone which gives a degree of elasticity to the capillary wall. Lutz *et al.* (82) found that endothelium did not respond to mechanical stimulation.

Folkow (44) summarizes current opinion in stating that "slow swellings of the capillary endothelium are sometimes observed, but are more probably to be looked upon as passive osmotic effects or deformations due to passive luminal changes, caused by variations in intravascular pressure."

Vasomotion

The word "vasomotion" has had extensive use since its first appearance in 1944 (20). The term was used at this time by Chambers and Zweifach to describe the spontaneous contractions and dilations of small arterioles (metarterioles) and the muscle cells of their branches (precapillary sphincters) in the rat mesentery, also called mesoappendix. It has subsequently come to be used to indicate observed diameter changes of any blood vessel.

Reports of variations in the caliber of small blood vessels have been in existence for almost as long as microscopic studies of them have been carried out. Special interest in this phenomenon was shown during the period of controversy over capillary contractility. In the years following the introduction of the rabbit ear chamber for microscopic observation of small blood vessels, numerous papers appeared in which spontaneous alterations in small blood vessels were described. Clark & Clark (29) spoke of the normal occurrence of spontaneous rhythmic contractions of arteries down to their smallest branches. Different arteries and parts of arteries were seen to contract at different rates (30). Sandison (106) reported rhythmic contractions of arterial vessels but saw no active contractions of veins or venules. Clark *et al.* (35) believed that an intact nerve supply was necessary for spontaneous contraction of the arterial vessels. Numerous other investigators reported periodic alterations of small vessel diameters (17, 57, 62, 141).

Chambers & Zweifach (20) described vasomotion in terminal arterioles and larger arterioles as irregularly periodic dilatations that are slower and more regular than the diameter changes seen in metarterioles and precapillary sphincters. When metarterioles were exhibiting vasomotion, they usually showed a decrease in diameter of about one-third, but were even seen to reduce the diameter by one-half or more. Other observations were that when a tissue was hyperemic, the dilator phase was most prominent, the constrictor phase dominating in ischemic tissue. No synchrony in vasomotion of neighboring arterioles was seen. Vasomotion was seen to continue in a metarteriole in the absence of blood flow through it. Also, diminished blood flow was followed by an increased dilator phase, while increased blood flow apparently brought on an intensified constrictor phase. Vasomotion was affected by local environmental conditions (irritation of the tissue caused vasomotion to disappear). Vasomotion also stopped when the animal was deeply anesthetized.

The recurrent vasomotion in metarterioles was considered by Chambers and Zweifach to be the factor which controls the rate of flow through the central vessels of a capillary bed while the vasomotion of precapillary sphincters controlled the flow through the true capillaries.

An extensive discussion of vasomotion by Nicoll & Webb (88) in 1946 described various types of caliber changes seen in both arterial and venous vessels. They suggested that the word vasomotion should be preceded by a suitable adjective to indicate a specific kind of change in vessel diameter, e.g., if the caliber change is brought about by contraction or relaxation of the vascular musculature, reference should be made to active vasomotion. If, on the other hand, caliber changes are produced by internal or external alterations of pressure not due to the activity of vascular musculature, reference should be made to passive vasomotion. Active vasomotion was further classified into three groups. "Tonic active vasomotion" was the term used to describe the maintained contraction of arteries, considered to be a tonus response. Superimposed on tone was the rapid contraction and relaxation of vessels that occur in response to nerve impulses. This was called irregular active vasomotion. The third type of movement was called rhythmical active vasomotion and referred to a regular alternation of contraction and relaxation of the vascular smooth muscle.

An analysis of the various types of active vasomotion, as given by Nicoll & Webb (88), follows. That arteries and arterioles possess tone, or are in a continuous state of active contraction, can best be demonstrated by noting the marked increase in their diameter that follows denervation. The diameters of arterial vessels in a denervated area have been shown to increase 27 to 29 per cent following nerve section (134). Nicoll and Webb state that the outstanding characteristics of tonic active vasomotion are its constancy and sluggishness, and suggest it may function to correlate blood vessel volume and blood fluid volume.

Irregular active vasomotion is characterized by rapid changes in the caliber of arteries and arterioles. The changes vary as to their magnitude and the length of time they endure. Such caliber changes are the direct result of impulses from the vasomotor nerves, controlled by the vasomotor center. Nerve section obliterates this type of activity. Nicoll and Webb are of the opinion that the function of irregular active vasomotion is to modify peripheral resistance and also to regulate the pressure gradient in the capillaries.

Rhythmical active vasomotion is the third type of activity seen in vascular beds. It has been observed in arteries, arterioles, precapillary sphincters, and veins. This regular alternation of contraction and relaxation of vascular smooth muscle cells has been shown to continue after denervation (129). It becomes more marked in the most peripheral vessel, the best example of it on the arterial side being at the level of the precapillary sphincters. It is the predominant type of activity shown by veins. In general, the more normal conditions are, the more outstanding is the rhythmical active vasomotion.

Nicoll & Webb (88) offer several reasons to give support to the hypothesis that this rhythmical activity is the result of an inherent property of smooth muscle cells rather than the response of vascular muscle to a rhythmical discharge from the vasomotor center or from humoral influences or physical conditions. The reasons are these: *a*) Terminal arterioles, precapillary sphincters, and veins exhibit rhythmical active vasomotion after denervation. *b*) This type of vasomotion is most highly developed in the venous muscular coat and precapillary sphincters, neither of which appears to be under direct control of vasomotor nerves. *c*) Adjacent vessels vary independently in the rate and magnitude of their rhythmical activity.

Rhythmical active vasomotion in veins is frequently powerful, reducing the vascular lumen to one-third or one-fourth of its resting diameter at the peak of contraction. The rate at which the contractions and relaxations occur is usually much faster than that observed in arterial vessels.

In later reports, Chambers & Zweifach (19, 22) discussed vasomotion and its relation to fluid exchange across the capillary wall. The term "vasomotion" was still used only in reference to spontaneous contraction and relaxation of the metarteriole and its branches. Vasomotion in the precapillary offshoots was said to produce alternate periods of varying hydrostatic pressure, thus greatly influencing fluid exchange in the capillary bed. When vasomotion was reduced or absent, blood pressure in the arterioles was spread through the numerous capillaries of the bed resulting in a slower flow through the capillaries and a subsequent accumulation of fluid in the collecting venules. Such a situation would create a sufficient back pressure to favor outward filtration. When vasomotion was active, blood flow went primarily through the arteriovenous pathways, bypassing the capillary vessels and producing a rapid flow in collecting venules. This bypassing of capillaries would favor drainage from the capillary network, a condition which would

increase inward filtration. In summarizing the significance of vasomotion in fluid exchange in the capillary bed, they state that the delicate vasomotor adjustments, which vary the surface area over which hydrostatic pressure may cause outward filtration, play a greater role than the differences between hydrostatic and colloidal pressure. Osmotic uptake, which is responsible for inward filtration, is dependent upon and reinforced by adequate venous outflow, a factor influenced by vasomotion.

Webb & Nicoll (130) refer to rhythmical active vasomotion as being the outstanding activity in the entire minute vascular bed and regard it as the principal factor of a local nature that regulates blood flow, and probably pressure, in the capillaries. All types of anesthesia reduce or abolish active vasomotion of the smaller vessels, and the authors suggest that this may be the reason why such activity is overlooked in many vascular studies. Active vasomotion is greatly reduced in conditions in which vascular flow is sluggish or irregular, or when the arterial pressure is low. Active vasomotion in arterioles can be augmented by sudden increases in intra-arteriolar pressure.

Active vasomotion was further discussed by Nicoll & Webb (89) in a paper in which investigations to determine the effect of environmental changes on active vasomotion were described. Arteries and the largest arterioles were said to show two types of active vasomotion, one being a slowly developing diameter change dependent on tonus and the other, a rapid diameter change dependent on the response of vascular muscle to nerve excitation. The smaller arcuate and terminal arterioles showed active vasomotion independent of nerve connection, and no classification of this activity into tonus changes or contractile responses was possible. However, two different types of muscular activity were seen in these small vessels, one being peristaltic waves sweeping along the terminal arterioles and the other being localized contraction of the precapillary sphincters.

The effect that active vasomotion has on blood flow through capillary beds depends on both its intensity and its duration. When constriction is not great enough to close the lumen completely, plasma and platelets continue to flow through the capillary vessels while the cellular elements are held back. This is referred to as "plasma skinning." When contraction of the vascular muscle is great enough to occlude the lumen, blood flow into the capillary nets is necessarily curtailed. The occlusion is normally temporary, resulting in intermittent flow through the capillary nets.

Veins and venules in the bat wing with smooth

muscle as a component of their walls exhibit marked active vasomotion. Nicoll and Webb describe the contraction as sharp, and one that sweeps along the vein as a peristaltic wave in a central direction. Each wave of contraction seems to originate at a distal valve and die out at the next valve central to it. Since the majority of valves are located at the confluence of tributaries, valve action and blood flow may seem unrelated due to asynchronous waves in two segments which are separated by their valves.

Two major tributaries which form a vessel may contract alternately. One tributary may empty into a segment ahead while the other tributary is relaxed. Irregular flow results when the frequency of contraction of the two tributaries is not coordinated. Single tributaries empty into a segment of the central vessel during its period of relaxation.

Nicoll and Webb adopt the concept that vascular smooth muscle cells possess an inherent ability to change their tonus or exhibit sudden contraction in response to changes in their immediate environment. In order to determine what environmental changes affect vascular smooth muscle, they observed changes in vasomotion in response to nerve stimulation, various gas mixtures, and temperature changes. They found that arteries and large arterioles responded to nerve stimulation with intense constriction. The smaller vessels, arcuate and terminal arterioles, precapillary sphincters, veins, and venules never showed initiation or modification of active vasomotion as a direct response to central impulses (129). Changing the local environment by flow of constant current between a single fluid electrode on the wing surface and an indifferent electrode produced alternate areas of marked constriction and dilatation on arteries and arterioles. Reversal of the current caused previously constricted areas to dilate and previously dilated areas to constrict. Nicoll & Webb (89) believe that this observation should be taken into account when interpreting responses to direct excitation of nerves with microelectrodes. Inhalation of carbon dioxide in a specific concentration proved to be a powerful stimulus of the contractile phase of active vasomotion. Variations in temperature showed the frequency of active vasomotion to vary directly with the temperature.

Changes in internal pressure of vessels have marked effects on vasomotion. Slow changes in pressure caused a vessel to adjust its tone gradually. Sudden increases in pressure, however, first caused a vessel to be distended mechanically and then to contract with great intensity. The contraction then spread along the

vessel as a peristaltic wave. Nicoll and Webb suggest that rhythmical variations in small arterial vessels may originate from sudden internal pressure changes at their origins from parent vessels.

Spontaneous changes in vascular tone, resulting from a rise or fall in internal pressure, were demonstrated. After blood flow to an area had been stopped by occlusion of a small supplying artery and was then allowed to resume, the vessels were first distended as they filled and then were seen to contract as a response, presumably, to the distention. Thus, blood was forced along to the next branches. Another example of adjustment of tone to a change in internal pressure is seen following denervation. The resulting dilatation of the main arteries probably raises internal pressure in the arterioles and increases their tone, sometimes reducing the flow through the arterioles to the capillary beds due to the reduction in lumen of the arterioles.

Nicoll and Webb express the opinion that the ultimate result of active vasomotion in terminal arterioles is to establish flow through capillary beds, the muscle cells of the terminal arterioles being the principal targets of changes in the local environment.

Active vasomotion in venules and veins may represent the adaptation of an inherent property of vascular smooth muscle to aid venous return. Nicoll and Webb suggest that this activity may be more widespread in vascular systems than is currently recognized. It may be more prominent in the veins of the bat wing than in small veins in other mammals due to the structure of the wing. Pressure within the veins seems to be the principal stimulus for the action.

Experimental evidence in confirmation of this proposal appears in the investigations by Wiedeman (135), in which veins in the bat wing were observed during elevations in venous pressure. Both diverting excess blood into a vein by ligating other venous pathways and infusing dextran to increase total volume caused a significant increase in cycles of venous vasomotion. Similar results were obtained when venous pressure was elevated by direct infusion with saline (136).

Although venous vasomotion is most prominent in the bat wing and shows a definite rhythmicity (fig. 24), spontaneous changes in pressure which are unrelated to arterial pressure or respiration have been demonstrated in small veins in hind legs of dogs (59, 137)

FIG. 24. Rhythmical variations in the pressure in a vein resulting from alternate contraction and relaxation.

(see fig. 25). Such changes have also been recorded in rabbit ear veins (unpublished data). (See fig. 26.) Recently, spontaneous changes in venous tone were recorded from the arm veins of man (16). Folkow has long supported the concept that rhythmic changes in tone of vascular smooth muscle is due to myogenic automaticity (42, 43, 45, 46). He points out (45) that because the rhythmical reactions seem to be completely unsynchronized, even in closely adjacent smooth muscle cells, it is improbable that they should be due to activity in a local syncytial nerve cell plexus in the vascular wall, as suggested by others (85). He is of the opinion (43) that intravascular pressure in a purely mechanical way to some degree will add "excitatory drive" to myogenic activity as proposed by Bayliss (10) and confirmed in Folkow's laboratory (42). Further confirmation appears in recent studies of forearm blood flow by Blair *et al.* (12).

At the present time then, in concurrence with Lutz & Fulton (81), the term "vasomotion" should refer to any active change in the diameter of a blood

vessel. It may be seen in one form or another where vascular smooth muscle exists, such as in arteries, arterioles, terminal arterioles, precapillary sphincters, venules, and veins. Any definite conclusions now as to the actual mechanism or mechanisms which initiate or control this vascular activity would be premature insofar as both direct and indirect evidence indicate that vasomotion in its various forms may be activated or modified through the central nervous system, reflexly or automatically, through myogenic automaticity, or through local metabolic factors.

This activity in venous vessels, especially if primarily dependent on myogenic automaticity excited by increased intravascular pressure, could serve as an effective aid to venous return from postcapillary vessels. On the arterial side it could serve as the regulator of blood flow through capillary nets as well as a protective mechanism whereby capillary vessels could not be subjected to sudden or prolonged increases in pressure which might rupture their thin walls.

FIG. 25. Spontaneous pressure waves in a small vein in the hindleg of the dog. [From Wiedeman (137).]

FIG. 26. Spontaneous pressure variations in a small vein of the rabbit ear.

SUMMARY

It is apparent, from the foregoing descriptions of structural organization of microcirculatory beds and regulation of the flow of blood through them, that the investigations have revealed more similarities than dissimilarities. Minor differences among patterns seem to be associated with the structural organization of the tissue in which the vessels lie, but the basic patterns remain the same.

Although presentation of an anatomical pattern that would be "typical" for terminal vascular beds would be likely to meet some resistance, it does seem necessary to agree on such features as arcuate or arcade connections, gradual divestment of spiral smooth

muscle cells along terminal arterioles to form capillaries, absence of direct association and control of capillaries through nerves, and similarity of the courses taken by small arteries and small veins. Also, certain functional activities which regulate blood flow and blood pressure through these beds must be considered as universal, these being spontaneous vasoconstriction and relaxation of arterioles, reversal of flow paths, alternation of routes of blood flow from arterial to venous vessels, and variations in the filling of capillary networks depending on local conditions. Future investigations may permit generalizations concerning the angles of branching in the arterial system and spontaneous vasomotion in the venous system.

CHAPTER CONTENTS

Resistance Vessels

Pressure-Flow Relations in Vascular Beds

Methods

Passive curvilinear relationship of pressure-flow plots

Mathematical relationships

Effects of Viscosity on Pressure-Flow Relationships

Effects of Extravascular Pressure on Pressure-Flow Relationships

Effects of Alterations of Venous Pressure

Autoregulatory Control of Resistance Vessels

Modification of passive pressure-flow relationship by autoregulation

Artifacts induced in autoregulation studies by pump perfusion schemas

Autoregulation in different vascular beds

Reactive hyperemia

Mechanisms responsible for autoregulation

Interpretation of change of vasomotor tone induced by constrictor and dilator agents in vascular beds which demonstrate autoregulation

Chemical Effects on Resistance Vessels

Extrinsic Control of Resistance Vessels

Effects of vasomotive agents on total resistance in a vascular bed

Segmental Resistances in Vascular Beds

Methods

Effects of Changes of Perfusion Pressure and Venous Pressure on Large Artery and Vein, and Distal Small Vessel Pressures

Effects of Extrinsic Agents on Segmental Resistance

Blood Volume in Vascular Beds (Vascular Capacity)

Methods

Effects of Various Factors on Vascular Volume

Estimation of Change of Vascular Volume Due to Extrinsic Influences

Pulsatile Changes in Vascular Volume

Interpretation of Vascular Behavior from Measurements of Flow, Pressure, and Vascular Volume

SINCE MOST VASCULAR BEDS do not permit direct microscopic study, indirect methods have to be used to evaluate them. In this chapter, the behavior of vascular beds is deduced from recordings of the rate of blood flow, the accompanying small vessel pressures, and the changes in vascular volume that occur as the result of varying the artery to vein pressure difference across the bed and as a result of other intrinsic and extrinsic influences.

Using the above measurements, the role of the terminal vascular beds is analyzed in terms of the behavior of those segments which determine the resistance to flow through the bed, i.e., the resistance vessels, and those segments which are related to the volume of blood contained in a terminal bed at any moment, i.e., the capacitance vessels. These functions of the terminal vascular beds are shown to be influenced by such physical factors as arterial perfusion pressure, presence of communication with collateral vascular beds, viscosity of the blood, extravascular pressure, venous pressure, by local autoregulation, and by extrinsic factors such as vasoactive agents and the autonomic nerves.

RESISTANCE VESSELS

Pressure-Flow Relations in Vascular Beds

METHODS. Pressure-flow relations in vascular beds have been studied by two principal methods. In one, the bed was perfused by a constant flow pump at various flow rates while the artery to vein pressure differences were recorded. More usually inflow or outflow from the vascular bed was recorded while the perfusion pressure was varied by using a constant pressure pump or by varying the degree of compression of the artery supplying the vascular bed. In most cases, the arterial and venous pressures were recorded together with the flow. Varying perfusion pressure by altering the degree of compression of the supplying artery has the advantage of providing a more nearly physiological situation with a minimum of complicating equipment, but does not allow exploration of the pressure-flow relationships above the animal's existing mean arterial pressure. Flow has been measured by orifice meters, rotameters,

FIG. 1. Diagram of collateral communications between a metered (cognate) capillary bed and collateral bed. *Inflow meter*—meter used to measure flow through the metered or cognate bed; *outflow meter*—meter used to measure the outflow from the metered or cognate bed; *anastomotic channels*—communications between cognate bed and collateral bed on the arterial and venous sides, respectively, of the metered or cognate bed. *A*—clamp used to occlude the inflow to the metered bed when perfusing it with fluid at various pressures; *B*—position where clamp might be placed to occlude the arterial supply to a collateral bed; *C* and *D*—positions where clamps must be placed in order to occlude the communications between cognate and collateral beds; *E*—point of occlusion to prevent outflow from a collateral bed. [Modified from Green *et al.* (41).]

FIG. 2. Relationship between perfusion pressure and arterial inflow. *I*—curve representing the direct relationship between arterial pressure and flow through the cognate bed when clamps were applied to the arterial anastomotic channels as at point *C* in fig. 1. *II*—artificial curve obtained if clamp *C* remains open when the arterial pressure supply to the cognate bed is varied. Note that at perfusion pressures higher than that existing in the collateral artery, the metered flow is greater than the flow through the cognate bed, and at pressures a little below that in the collateral artery, the inflow is less than that through the cognate bed while at some lower perfusion pressure backflow is recorded. *III*—artificial curve obtained if clamps are applied to the arterial supply to the collateral bed as at point *B* in fig. 1. Note that while no backflow is obtained, the metered inflow is greater than the flow through the cognate bed at all levels of pressure, and the magnitude of the error increases with the perfusion pressure. [Modified from Green *et al.* (41).]

electromagnetic flowmeters, drop recorders, and Gaddum-type ordinate recorders (20, 27–29, 46).

In studying pressure-flow relationships in intact vascular beds, it is necessary that all anastomotic communications with collateral vascular beds be occluded. If they are not, then, during measurement of inflow at perfusion pressures above the animal's mean arterial pressure, part of the perfusion fluid will leak across the anastomotic channels from the cognate into collateral vascular beds (fig. 1-a), giving an inflow which is higher than the true flow through the cognate bed (fig. 2-II). Similarly, at perfusion pressures below the animal's mean arterial pressure, blood will leak across the communicating channels from the animal's collateral arteries to the metered (cognate) vascular bed (fig. 1-b); as a result the metered inflow will be less than the actual flow through the cognate bed. At some lower pressure inflow in the metered artery will cease and, at still lower pressures, backflow from the artery will be recorded, thus giving an entirely false picture of the

behavior of the cognate vascular bed (41). Analysis of the rate of backflow may be useful, however, as a measure of the effectiveness of existing communications between cognate and collateral arteries.

Errors analogous to those on the arterial side may occur when recording venous outflow, due to the presence of postcapillary communications with veins draining collateral vascular beds (fig. 1-c, d).

PASSIVE CURVILINEAR RELATIONSHIP OF PRESSURE-FLOW PLOTS. The simplest relationships between pressure and flow occur in vascular beds which do not show autoregulation such as skin or "nonreactive" hind limbs (46, 88, 115) or the pulmonary vascular bed (78). All such curves are curvilinear with the convexity toward the pressure axis (fig. 3). In such studies changes of vasomotor tone have occurred spontaneously (46) or have been induced by infusion of epinephrine (88). With increase in vasomotor tone the curves rotate toward the pressure axis so that for any given level of pressure, flow is less (fig. 3). In all such experiments, using blood as the perfusate, the curves approach the zero flow axis asymptotically. A "critical closing pressure," such as was described by

Burton (6) and others (10, 37) was not noted in the above studies (see also 32, 35, 64). Curves of this type may be said to exhibit a "passive" relationship between pressure and flow.

MATHEMATICAL RELATIONSHIPS. When the data from the above experiments are plotted on log-log paper, approximately straight lines with varying foci and slopes are obtained (fig. 3). It appears, therefore, that the mathematical relationship between flow and pressure is a power function

$$F = c \times P^n$$

where F = flow in ml per min, c is a constant, P = arteriovenous pressure difference in mm Hg, and n is an exponent having a value between 1 and 3 (46). The lowest value of n and the highest value of c were found at "low vasomotor tone" (fig. 4, point A) and vice versa (fig. 4, point C). Levy & Share (74) have confirmed these findings and demonstrated that with maximal dilation induced by a 10-min period of ischemia and subsequent perfusion with hypoxic blood, the value of n is 1.0. The relationship of c to n

FIG. 3. Plots of the arteriovenous difference pressure vs. the blood flow in a cutaneous (saphenous) bed at three levels of spontaneous "vasomotor tone." *Left half*, plotted linearly; *right half*, plotted on log-log paper. *Triangles* represent the lowest level of vasomotor tone; *circles* represent an intermediate level and *squares*, the highest level of vasomotor tone. The figures in the upper left-hand corner of the graph represent the parameters for the straight lines reproduced in the log-log plot and for the curvilinear lines reproduced in the linear plot. Flow—ml/min; pressure—mm Hg. [Modified after Green *et al.* (46).]

FIG. 4. Log-log plots of the interrelations of the parameters from fig. 3. Open circles—plot of the relationship of the resistance at a flow of 5 ml/min to the constant c ; solid circles—plots of the relationship of the resistance at a perfusion of 100 mm Hg to the constant c ; open triangles—plots of the resistance at a flow of 5 ml/min to the exponent n ; solid triangles—plots of the relationship of the resistance at a pressure of 100 mm Hg to the exponent n ; x —plot of the relationship of the constant c to the exponent n ; points labeled A, B, and C refer to curves A, B, and C, respectively, in fig. 3. Ordinate scale applies to resistance at a flow of 5 ml/min (PRU_F), to resistance at a perfusion pressure of 100 mm Hg (PRU_P), and to n . Abscissal scales apply to n (left graph) and to the constant c (right graph). See Table 1 for further identification of symbols.

in the above experiments (46) was also approximately linear in a log-log plot (fig. 4).

There are at least two possible explanations for a value of n greater than 1. *a*) The apparent viscosity of whole blood decreases as the pressure difference across a length of rigid capillary tubing 0.3 mm or less in diameter is increased, i.e., as flow increases (40); this is due probably to the red cells being clumped progressively closer together as a solid core in the middle of the tube as the rate of flow increases, leaving a sleeve of plasma adjacent to the intima of the blood vessel and thus reducing viscous drag. *b*) Other factors being constant, flow through a conduit is proportional to the fourth power of the diameter. If, with increasing internal pressure, a slight but progressive increase in the diameter of the resistance vessels occurs, then flow through vascular beds containing such distensible structure will increase in proportion to some power of P greater than 1 [Green *et al.* (46); Folkow (27–29, 32)]. From the data in figure 4 it appears that these effects become augmented with increase in “tone” of the resistance vessels. Computations, based on data compiled by Burton (7), indicate that an increase of internal

pressure from 0 to 102 mm Hg in an arteriole might increase the cross-sectional area sufficiently that the relative conductance would be 146 per cent of that at zero pressure, i.e., at the unstretched diameter (fig. 5). However, Baez & Lamport (2) report that arterioles of 34 to 42 μ diameter showed essentially no change in diameter under considerable pressure variation. They did note selective closing of pre-capillary sphincters at positive pressures.

The relationship of resistance to flow, PRU (peripheral resistance unit = P/F = mm Hg (ml/min)), to either flow or A-V pressure difference was also a power function in the above studies; for each level of tone the resistance to flow varied inversely with either flow or perfusion pressure (table 1). Since both the constant and the exponent varied as vasomotor tone changed, the relationship of resistance at one level of tone to that at another (B/A; C/A in table 1) was also a power function of either flow or pressure; this ratio, which was inversely related to pressure and flow, can be expressed as a number if the same pressure (i.e., 100 mm Hg = PRU_{P100}) or flow (i.e., 5 ml/min = PRU_{F5}) is used for each curve (table 1).

FIG. 5. Relationship of internal pressure to radius in elastic tubes. Radius is expressed as ratio of the radius at any pressure to the unstretched radius (r/r_o). Pressure is plotted over the range from zero to 1, 1 representing that pressure at which the vessel extends indefinitely, and zero the pressure at which the vessel is unstretched. Corresponding values of actual pressure, opposite the bracket, are given in mm Hg; below this is given the per cent extension of the vessel at each of the levels of relative pressure, and below that is given the conductance which the vessel would have relative to that in its unstretched state. Conductance is expressed as the ratio of flow to pressure drop along unit length of the vessel. These plots are calculated from data in Burton (7).

It is of interest that c' vs. n' and c'' vs. n'' (table 1) both plotted as straight lines on log-log paper, as did c vs. n in figure 4. It is of interest also that the lines on the log-log plot in figure 3 approach each other at high pressures and flows. As a result, if the data could be extrapolated to such values, a point would be found at which the resistance in state B would equal that in A (i.e., $P = 5,000$, $F = 16,000$) and another point at which the resistance in state C would equal that in A (i.e., $P = 2,950$, $F = 5,400$). In a log-log plot these two points are so close together that a common point of intersection could be assumed for all three lines—A, B, and C. This suggests that a rise of perfusion pressure acts to overcome the constrictor tone, and that this effect is proportionally greater the higher the vasomotor tone.

From the above data it appears that the most satisfactory method for defining "vasomotor tone" in passive vascular beds is by means of a pressure-flow plot, or by means of the equation for such plot. The best quantitative expression for the comparison of vasomotor tone at one moment with that at another is to determine the plot of the pressure-flow relationship during a control phase of vasomotor tone and to

compare this with a similar plot obtained in the experimental period (see fig. 3 and table 1, columns B/A, C/A, lines II and III). Often this mode of expression is impractical because of the difficulty in maintaining vasomotor tone constant, particularly in the experimental period. A more practical compromise for expressing change of vasomotor tone may be to determine the pressure-flow relationship over a suitable range of pressures and/or flows during the control period and to compare isolated experimental observations of pressure and flow with this control curve (see figs. 21 and 22 and table 1, columns B/A, C/A, lines IV, V).

From an inspection of figures 3 and 4 and table 1, it appears that comparison of the experimental perfusion pressure with that required in the control period to induce the same rate of flow (table 1, lines III and V) may provide a ratio which approximates the apparent separation of the lines more nearly than does the ratio of pressures at constant flow (table 1, lines II and IV). This would provide merit in perfusing passive (nonautoregulating) vascular beds at a constant rate of flow while recording the

TABLE 1. *Mathematical Relationships Between Resistance and Pressure and Between Resistance and Flow*

| V | PRU_{F_5} | 10.1 | 29.7 | 41.8 | 2.9 | 4.14 |

The columns correspond to the curves: A = solid triangles; B = solid circles, and C = solid squares in fig. 3. PRU_P = resistance in mm Hg/(cc/min) expressed as a function of the arteriovenous difference in pressure in mm Hg; PRU_F = resistance expressed as a function of the rate of flow; $PRU_{P_{100}}$ = resistance computed at an arteriovenous pressure difference of 100 mm Hg; PRU_{F_5} = resistance calculated at a flow of 5 cc/min; B/A and C/A = ratios of values in columns B and C, respectively, to those in column A. *Note*—columns B/A and C/A: for lines II and IV these values are also reciprocal ratios of flow at constant arteriovenous pressure difference and for lines III and V they are also direct ratios of arteriovenous difference of pressure at constant rate of flow.

$$F = c \times P^n$$

$$PRU_P = \frac{P}{F} = \frac{P}{c \cdot P^n} = \frac{c^{-1}}{P^{n-1}} = \frac{c'}{P^{n'}}$$

$$PRU_F = \frac{P}{F} = \frac{F^{1/n}}{c^{1/n} \cdot F} = \frac{c^{-1/n}}{F^{1-1/n}} = \frac{c''}{F^{n''}}$$

The data in this table were computed from results reported by Green *et al.* (46).

arteriovenous difference of pressure during experimentally induced changes of vasomotor tone.

On the other hand the convergence of the pressure-flow plots at high pressures, discussed above, suggests a secondary influence of change of perfusion pressure on vascular distensibility and measured resistance. On this basis there is merit in using a constant perfusion pressure and allowing the flow to vary with experimentally induced changes of vasomotor tone rather than keeping the flow constant and allowing the perfusion pressure to be the dependent variable. At present we cannot find sufficient grounds for a decision between the two methods of perfusion when studying "passive" vascular beds.

In those vascular beds which show autoregulation (p. 948) anything which induces a change of flow, i.e., alteration of perfusion pressure, tends to be countered by an active change of vasomotor tone which will tend to maintain flow constant. In this type of bed it is particularly desirable to have data on the control steady-state pressure and flow relationships in order to make adequate quantitative comparisons with experimental data.

Effects of Viscosity on Pressure-Flow Relationships

The viscosity of blood relative to that of water increases nonlinearly with red cell concentration,

FIG. 6. Mean and probable error of the apparent viscosity of blood relative to saline in a glass viscometer and in the hind limb of a dog at different corpuscular concentration. [Redrawn after Whittaker & Winton (115).]

varying from around 2 with pure plasma to around 5 at high hematocrit readings when measured in a low velocity viscosimeter (fig. 6). Lower relative viscosities are obtained with high velocity viscosimeters and still lower relative viscosities are noted in perfused organs. The relative viscosity in the latter two systems decreases as the pressure difference and flow rate are raised. Most of the viscosity of normal blood is due to the suspended red cells, but the effect of the cells is slight until the hematocrit begins to exceed 30 per cent (40, 74, 115); however, the plasma proteins, particularly the globulins, contribute significantly (112). In terms of effective oxygen delivery to the tissues, a hematocrit of around 45 appears to represent the best compromise between viscosity and O_2 carrying capacity (50).

Effects of Extravascular Pressure on Pressure-Flow Relationships

In most vascular beds extravascular pressure exerts little effect. However, in muscle vascular beds, a marked increase in resistance to flow occurs with contraction. This is exemplified best in the myocardium in which during systole a rise in resistance

FIG. 7. Records of systemic arterial pressure (BP), and lateral pressure (CP) and moment-to-moment flow (F) in the descending ramus of the left coronary artery during the period labeled "flow." During the period labeled "peripheral pressure" flow was interrupted by occlusion of the coronary artery inflow proximal to the site of pressure measurement so that the gauge recorded "peripheral coronary artery pressure." Note that the latter pressure begins to rise during the phase of isometric contraction that precedes the rise of systemic arterial pressure, and that the peripheral coronary pressure begins to fall with the onset of protodiastole, just before the incisura in the systemic arterial pressure. [Reproduced in modified form from Denison & Green (19).]

occurs which closely parallels intraventricular pressure in magnitude and duration, as shown in figure 7 (19, 43).

Coles & Gough (10) applied external pressure to a cup applied to a digit while observing the capillaries with a microscope. They noted that arrest of capillary flow occurred consistently at cup pressures of 32 to 60 mm Hg in subjects with mean brachial artery pressures of 80 to 120 mm Hg obtained with the sphygmomanometer. They spoke of the pressure at which flow ceased as the critical closing pressure and reported that it rose with the arterial pressure in hypertensives and fell with digital vasodilation induced by body warming. The use of the term "critical closing pressure" in this sense seems to us to be ambiguous. Quite possibly, in their experiments the pressure decreased progressively from the brachial artery to the small digital arteries. If this were the case the vessels in the digits may have collapsed when the extravascular pressure just exceeded the intravascular pressure. However, since the true intraluminal pressure of the vessels which close was unknown, the role of the elastic forces producing critical closure (see Burton, Chapter 6, vol. 1, sect. 2, of this *Handbook*) as against the role of simple mechanical collapse can hardly be differentiated. This makes it quite difficult to assign a figure for the critical closing pressure if indeed one may use that concept here.

Cerebrospinal fluid pressure may have a tendency to vary directly with cerebral blood flow; however, artificially induced changes of cerebrospinal fluid pressure have little effect on flow unless the pressure is elevated above arterial pressure (76 and unpublished data).

Effects of Alteration of Venous Pressure

When extremities were perfused with varying pressures, while venous pressure was altered simultaneously so as to maintain artery to vein pressure difference constant, flow still varied with the level of the arterial pressure (89). The authors conclude that some vascular structures were dilated as the arterial (and total) pressure throughout the vascular bed rose. In the supine anesthetized dog, inspiration was accompanied by a rise of intra-abdominal pressure and of small vein pressure in the hind leg. Widely opening the abdomen abolished both (113). The small vein pressure effects apparently were transmitted peripherally from the inferior vena cava.

FIG. 8. Autoregulation in the cerebral vascular bed of the dog. *Above:* records representing vertebral arterial pressure in mm Hg and cerebral venous outflow in ml/min. *Below:* heavy solid line, relationship between the cerebral venous outflow and the mean of the carotid and vertebral artery pressures minus the cerebral outflow pressure during autoperfusion of the brain from the carotid arteries. The perfusion pressure was regulated by means of clamps on the carotid arteries. Light solid line, similar relationship but during the perfusion of the carotid arteries with an artificial perfusion system.

Autoregulatory Control of Resistance Vessels

For the purpose of this chapter, we propose that the term autoregulation be defined to include all processes which operate locally in a vascular bed to maintain some factor constant in the face of various externally or internally induced stresses. The factor which is kept constant, i.e., the controlled variable (see below) may be blood flow, or the tissue concentration or tension of some nutrient (O_2 , etc.) or some metabolite (such as CO_2). As proposed here, the term autoregulation would exclude extrinsic mechanisms such as reflexes involving the central nervous system, variation in arterial pressure, or changes in hormone activity.

The activity of autoregulatory mechanisms has been studied by subjecting isolated or semi-isolated organs to stresses such as changes in arterial perfusion pressure or blood gas content, or by altering tissue metabolism while recording the resulting change, or lack of change

in blood flow, venous gas content, or the content of other metabolites.

MODIFICATION OF PASSIVE PRESSURE-FLOW RELATIONSHIP BY AUTOREGULATION. In many vascular beds, the above-mentioned power relationship between perfusion pressure and flow in passive vascular beds is modified by occurrence of autoregulation. The insert in the upper portion of figure 8 shows recordings of blood flow in the brain obtained during autoperfusion (76 and unpublished data). In these studies, carotid artery inflow pressure was lowered abruptly from 84 to 44 mm Hg; after flow stabilized, perfusion pressure was returned to the control level. Immediately upon lowering perfusion pressure, flow dropped from 12.5 to 8.5 ml per min, then rose to a stabilized level of approximately 10 ml per min. Upon restoration of control pressure, flow rose abruptly to 16 ml per min and then stabilized at approximately its original level of 12.5 ml per min. The rise in flow following the initial decline probably was due to vasodilation, and the secondary decline in flow following restoration of the original perfusion pressure probably was due to vasoconstriction. When data from such experiments are plotted they yield a series of curves such as are reproduced in figure 9.

The heavy line in the graph in figure 8 corresponds to the heavy line in figure 9 and is a plot of the stabilized flows at each level of perfusion pressure from 85 to 15 mm Hg. This line is almost horizontal, indicating an almost constant level of stabilized flow over the pressure range of 80 to 35 mm Hg. In view of the observations in figures 3 and 4, this finding can be explained only by assuming some reactive change in the diameter of the resistance vessels so as to compensate for alteration of perfusion pressure (76 and unpublished data). The mechanism responsible for compensation for pressure change has been termed local reaction of the arterial wall, reactive vasodilation, intrinsic regulation, autoregulation and "genuine autoregulation" (3, 27-29, 36, 46, 63, 66, 72, 90, 92, 99, 105, 109, 111).

Observations, similar to those in the brain, were recorded in artificially perfused skeletal muscle vascular beds (fig. 10). At pressures above normal the pressure-flow relationship was curvilinear and similar to that described for skin (fig. 3) and the resistance to flow, after stable flow was established, increased progressively as perfusion pressure was lowered. However, as perfusion pressure dropped below 100 mm Hg the curve began bending more sharply to the left so as to become approximately horizontal to the pressure axis, and the stabilized resistance to flow

FIG. 9. Sequential flow readings following a series of square wave changes of perfusion pressure in a vascular bed showing autoregulation. The pressure-flow points are numbered successively A_0, A_1, A_2, A_3 , and A_4 for the first square wave change of pressure (on both insert and graph). The points for the second pressure change are numbered similarly B_0-B_4 and for the third, C_0-C_4 . Light solid line represents the pressure-flow relationship which would be found if vasomotor tone remained constant at the level which existed during perfusion at a pressure corresponding to A_0 for a period of time sufficient to establish a steady-state flow at this pressure. Dash-dot line represents the corresponding pressure-flow plot which would be found if the vasomotor tone were to remain constant at a level corresponding to that found when steady-state flow was established at a perfusion pressure corresponding to point B_2 . Dash-dash line represents the pressure-flow plot which would correspond with the steady-state flow established for perfusion pressure A_2 assuming no change in vasomotor tone were to occur with subsequent change of perfusion pressure. These three plots then represent three levels of vasomotor tone. Heavy solid line represents the actual "steady state" pressure-flow relationship after reactive changes have occurred in the vasomotor tone following each change of perfusion pressure; it is the plot characteristic of autoregulation.

decreased with further lowering of perfusion pressure down to about 50 mm Hg. This progressively decreasing resistance tended to maintain flow relatively constant over the range of arterial pressure from 90 down to approximately 50 mm Hg. Below 50 mm Hg arterial pressure, flow dropped rapidly and approached zero at a pressure of 10 to 20 mm Hg.

When the pressures and flows in figure 10A are plotted on log-log graphs (fig. 10B), the portion corresponding to the pressures above 90 mm Hg plots as a straight line with a slope greater than 1; this portion of the curve corresponds to a "passive" relationship between pressure and flow (see above). On the other hand, in the range between 50 and 90 mm Hg the slope is less than 1. In the equation $F = cP^n$, the corresponding values of n are greater than and less than 1, respectively. Values for n of less than 1 are characteristic of autoregulation (28, 29).

ARTIFACTS INDUCED IN AUTOREGULATION STUDIES BY PUMP PERFUSION SCHEMAS. Failure to detect autoregulation in vascular beds has been attributed to occurrence of some alteration in the vascular bed as a result of changes in the blood due to contact with artificial structures or to traumatization of the blood by perfusion pumps (28, 29, 66). This effect is noticeable particularly in the cerebral vascular bed, as shown in figure 8 (76 and unpublished data).

The heavy line in figure 8 represents the stable pressure-flow relationship in a cerebral vascular bed during an initial study when the pressure was regulated by compressing the arteries supplying the brain. The light line gives the stable pressure-flow relationship during a subsequent period when a perfusion pump was inserted in the arterial inflow circuit. With the perfusion pump in operation, flow at all levels of pressure was significantly above that with the brain perfused directly from the heart. Furthermore, the flow did not remain constant but increased regularly

FIG. 10. Plots of the relationship between blood flow in a skeletal muscle vascular bed in the dog and the arterial perfusion pressure (arterial pressure minus venous pressure). A: linear plot; B: log-log plot. Pressures were varied from the control, at approximately 160 mm Hg, to successively lower or higher pressures and returned to the control following each determination at the experimental pressure. Each point represents the data after the flow had stabilized at the new pressure.

as the perfusion pressure was varied from 40 to 100 mm Hg. These findings suggest that a vasodilator effect induced by the pump prevented the increase in vasomotor tone that occurs normally as perfusion pressure is increased from 35 to 85 mm Hg (76 and unpublished data). Autoregulation may be absent from kidney and skeletal muscle beds in the presence of strong extrinsic stimuli (69, 73, 111), and from intestine during the initial period of the perfusion (66).

AUTOREGULATION IN DIFFERENT VASCULAR BEDS. Autoregulation in brain has been both denied (22, 95) and supported (8, 26, 39, 71, 76). Autoregulation has been observed in the kidney by many investigators (58, 59, 65, 72, 97, 99, 105, 110, 116). Failure to note autoregulation when the kidney(s) is perfused via the aorta could be due to failure to ligate the two lumbar arteries that arise from the aorta between the right and left renal artery origins (58).

Fairly potent autoregulation was observed in skeletal muscle (27–29, 46, 109) and modest autoregulation in the intestine (66, 68, 101, 102) and in the liver (36, 92); but significant autoregulation was not elicited in skin (Rapela and Green, unpublished data). It would be anticipated that myocardium would demonstrate prominent autoregulation; however, to date this has not been demonstrated with certainty (17, 21, 24, 43, 84, 85, 98).

FIG. 11. Records of flow in a dog skeletal muscle vascular bed and in a cutaneous vascular bed (saphenous bed) before and following a 1-min period of occlusion of the arterial inflow. Arterial pressure upstream from the point of occlusion remained constant during these studies.

FIG. 12. Bar graphs of the magnitude of the reactive hyperemia computed from data such as that in fig. 11. The ordinate values are the maximum flow during the postocclusion period expressed as per cent of the control flow. The width of each bar represents approximately the proportion of the cardiac output which normally flows through the indicated vascular bed; total is the integrated effect for the body as a whole. [Reproduced from Green & Kepchar (45).]

REACTIVE HYPEREMIA. Occlusion of the arterial supply to a skeletal muscle bed for 30 sec to 1 min is followed, upon restoration of the original pressure, by a marked overshoot of flow (fig. 11, upper curve). This response has been thought to represent a local reaction of the arterial wall to changes in internal pressure (3). However, it is more likely that the overshoot represents a special manifestation of autoregulation. When muscle contracted during a period of occlusion the excess O_2 delivery during the period of reactive hyperemia underpaid the O_2 debt accumulated during the period of occlusion, if the muscle was at rest during the occlusion the reactive hyperemia overpaid the debt (9, 108).

Momentary overshoot of flow after a period of occlusion was noted on occasion in the dog's paw. However, comparison of weight changes (see below) with the integral of the flow during the period of overshoot suggested that the overshoot represented refilling of small vessels, which had emptied by elastic recoil into the vein during the period of arterial occlusion (114 and Rapela and Green, unpublished data).

Reactive hyperemia following temporary occlusion of the arterial supply is maximal in myocardium and brain (49, 84; and Rapela *et al.*, unpublished data), active in skeletal muscle, present in the mesenteric artery bed and in kidney, but is almost absent in spleen, skin (fig. 11, lower curve), hepatic artery, and portal vein vascular beds (45), as shown in figure 12.

MECHANISMS RESPONSIBLE FOR AUTOREGULATION. *Feed-back loop.* 1) General concept. The engineer's feedback loop provides a convenient way to visualize control mechanisms (fig. 13). The controlled variable is that

measurement which the controlling mechanism is attempting to keep constant (such as arterial pressure, or tissue O_2 tension). The level of the controlled variable may be disturbed by various loads, i.e., bleeding in the case of arterial pressure, or variations of tissue metabolism in the case of tissue O_2 tension. The detector senses continuously the magnitude of the variable and feeds the information to a summator or discriminator where it is compared with the desired value (set point) and modified by signals from other loops. The resulting signal is then fed to an effector which controls the activity of whatever process is necessary to maintain the controlled variable constant.

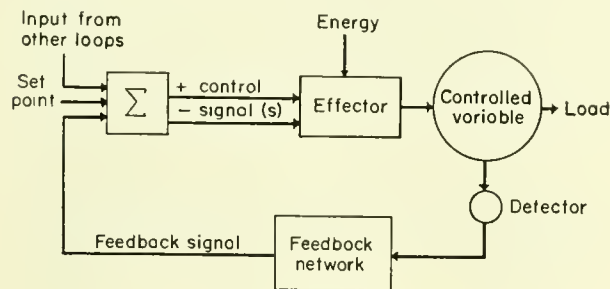

FIG. 13. Schematized diagram for a feedback loop (see text or discussion).

2) Present evidence suggests that, in skeletal muscle, a possible controlled variable in the feedback loop for autoregulation is the tissue oxygen tension (69). The detector is unknown; but the feedback loop may involve adenine formed from adenosine triphosphate (ATP) in the presence of insufficient oxygen. The summation point may be the receptor site on the arteriolar smooth muscle, and the effector may be the arteriole which controls the rate of blood flow by means of which the controlled variable is regulated (5).

3) There are other possible controlled variables in the feedback loop for autoregulation. The increased flow that occurs in skeletal muscle during and following a tetanic contraction may represent another manifestation of this pattern of autoregulation although axon reflexes in the sympathetic nerve supply have been postulated as playing a role (62). The vasodilation that occurs in skeletal muscle during activation of the patellar reflex is thought to be due to the same mechanism as that of the postcontraction hyperemia (107).

The controlled variable responsible for autoregulation (and reactive hyperemia) may vary with different vascular beds. Tissue oxygen tension appears to be the controlled variable in the myo-

FIG. 14. Left anterior coronary artery inflows in the dog. A: in response to a 90-sec period of breathing 5% O_2 . B: effects of an intra-arterial injection of 1 mg of sodium cyanide. Note the calibration for flow is nonlinear (the deflection is approximately proportional to the square of the flow). [Modified after Green & Wegria (49).]

cardium and skeletal muscle, since reducing the oxygen content of the arterial blood produces a rather large increase in coronary (fig. 14A) and in skeletal muscle flow, whereas there is almost no change in flow in either bed when arterial blood CO_2 content is increased (12, 49). The fact that coronary flow is influenced more by coronary artery O_2 content than tension (51) is not incompatible with the concept that tissue O_2 tension is the controlled variable. The feedback loop in the heart must involve something other than O_2 tension, since intra-arterial injection of cyanide causes as great an increase of coronary flow as does hypoxia (fig. 14B) (49).

The increase in blood flow in the brain in response to decreased arterial blood oxygen content is relatively minor compared to that which follows an increase in CO_2 content (fig. 15) (44), suggesting that brain CO_2 tension may be the controlled variable for this tissue.

Elevation of arterial blood hydrogen ion concentration decreases resistance to flow through cutaneous (18, 25), renal (23), and skeletal muscle (18) vascular beds. Depression of the hydrogen ion concentration below normal is accompanied by increase of resistance to flow in skin (18, 25) and kidney (23); however, in skeletal muscle depressed hydrogen ion causes about the same degree of decrease of resistance to flow as

does an elevation of hydrogen ion concentration (18). Effects of hydrogen ion concentration on myocardial blood flow are reported to be the reverse of those in skin and kidney (38). These findings suggest that hydrogen ion might be one of the controlled variables in autoregulation.

Role of nervous system in autoregulation. Autoregulation is prominent in denervated vascular beds. High activity in the extrinsic nerves may even minimize or prevent manifestation of autoregulation; for instance, central reflex effects of hypoxia may overpower the local dilatory effect in the anesthetized dog's innervated skeletal muscle vascular bed (75) (see also p. 943). Autoregulation in kidney is not abolished by procaine anesthetization, adrenergic blocking agents, or gamma-aminobutyric acid (111), suggesting that the feedback loop contains no essential link that responds pharmacologically as does nervous tissue.

The behavior of cerebral blood flow in response to changes of perfusion pressure (see above) cannot be stated conclusively to represent strict autoregulation, since in these studies a reflex neural mechanism was not excluded. However, no influence of extrinsic autonomic constrictor nerves upon cerebral blood flow has been demonstrated conclusively (45), and therefore, it is unlikely that an autonomic reflex is involved in the cerebral studies.

Myogenic theory of autoregulation. Bayliss (3) proposed from studies of dog's hind legs and isolated arteries, that the arterial wall responds directly to a rise of intraluminal pressure by an increase in its state of contraction (or tone) sufficient to bring about a reduction in the lumen of the vessel (and presumably therefore, a decrease in the flow through the vessel). This concept received support from Johnson (66) who failed to find an appropriate correlation between change in the O_2 concentration of the venous blood draining an isolated segment of gut and the occurrence of a decreased resistance to flow as perfusion pressure was lowered. Since he found, also, no correlation with nerve activity, gut contraction, or presence of metabolites, Johnson concluded that the autoregulatory change of flow represented a myogenic response. Waugh & Shanks (111) observed that hypothermia (3–10 C), intrarenal infusion of chloral hydrate, or high concentrations of procaine abolished autoregulation but that anoxic perfusion did not depress the autoregulatory reaction; since nerve block also did not interfere (see above) they concluded that renal autoregulation is due to "myogenic vasomotion." Folkow (27) also postulated a myogenic

FIG. 15. Records of cerebral venous outflow and systemic arterial pressure during a 4.5-min period of breathing 8% O_2 (upper pair of curves) and in response to a 5-min period of breathing 10% CO_2 in 90% O_2 (lower pair of curves) in the dog. Brain was perfused directly from the aorta.

basis for autoregulation in skeletal muscle since it was not abolished by breathing oxygen at either high or low partial pressure. It should be noted that the above conclusions regarding the myogenic theory are based solely on negative evidence. It seems quite unlikely to us that a vascular wall could respond appropriately to changes of intraluminal pressure per se.

Physical factors related to autoregulation. Renal blood flow at a given level of arterial pressure was the same whether the perfusion pressure was steady or pulsatile. Autoregulatory changes in resistance were observed with both types of perfusion (93).

A rise in renal interstitial and intrarenal venous pressure was found to parallel an elevation of arterial pressure over the "autoregulatory range." This finding is proposed as the explanation for the autoregulatory rise in renal vascular resistance that accompanies an elevation of renal arterial pressure (65, 96). On the other hand, two other groups of investigators (81, 111) could not account for the observed autoregulation in their dogs' kidneys on the basis of such changes in intrarenal tissue or venous pressures.

An increase in postglomerular viscosity which parallels glomerular filtration rate (116) has been proposed to explain the "autoregulatory" increase in renal vascular resistance that accompanies a rise of arterial perfusion pressure above 80 mm Hg. However, Selkurt *et al.* (100) found that arterial perfusion pressure could be varied between 100 and 160 mm Hg without significant change in blood flow (para-minohippurate clearance), glomerular filtration rate (creatinine clearance), or filtration fraction. In their experiment, therefore, the postglomerular viscosity remained unchanged, and the autoregulatory variation in renal vascular resistance must have occurred solely in the preglomerular vessels. An increase in effective viscosity of the blood flowing in the cortical layers due to plasma skimming in the intralobular arteries (cell separation theory) has been proposed by Pappenheimer & Kinter (72, 87) to explain renal autoregulation. However, Waugh & Shanks (111) were able to demonstrate autoregulation in the kidney using a cell-free perfusate, so long as the fluid contained plasma. Evidently simple physical phenomena will not serve to explain renal autoregulation.

Enlargement of collateral communications following occlusion of the cognate arterial supply as a manifestation of autoregulation. It is well known that, following occlusion of an artery, collateral communications between the cognate bed and collateral arteries enlarge rapidly

until within a few hours to weeks they can supply almost a normal rate of flow to the cognate bed. Such enlarged channels are demonstrated beautifully during arteriography. The dilation of the communicating channels may be considered a special case of autoregulation, although almost nothing is known regarding its mechanism of action. It does not appear to be brought about by any special change in arterial pressure proximal to the occlusion. The enlargement of the communicating channels is more likely related to an increased rate of flow or enhanced pressure drop through the communicating channels (60).

Summary of present status of feedback control of autoregulation. Though the mechanism of the autoregulation of blood flow has not been established as yet, the following trends may be stated. *a)* Most likely there is more than a single factor involved and the predominant one may vary in different organs. In the kidney, for example, maintenance of a constant glomerular filtration rate may be more significant than satisfaction of the metabolic requirements of the organ; consequently the sensing mechanism to regulate blood flow should be related directly or indirectly to glomerular filtration. The juxtaglomerular apparatus may serve this function (97, 111). In organs such as a skeletal muscle and the heart, metabolism fluctuates rapidly; in these a mechanism must be available to allow adaptation of flow to the varying metabolic demands. Such mechanism should be capable of sustaining the metabolic activity in the face of fluctuations in arterial pressure. In either case the sensing mechanism may detect the adequacy of supply (i.e., tissue O_2 tension) or the adequacy of removal of metabolic products (i.e., tissue CO_2 tension). It appears probable that the former is sensed in heart and muscle and the latter in the brain. *b)* Autoregulation may be absent in vascular beds such as the paw or skin which have very low metabolic requirements. *c)* Whatever the mechanism of autoregulation, at times it appears to be dependent on the presence of certain "normal factors" in plasma required for maintenance of "normal vascular tone," and at other times to be masked by certain "abnormal factors" which may induce either "abnormally high" or "abnormally low vascular tone."

INTERPRETATION OF CHANGE OF VASOMOTOR TONE INDUCED BY CONSTRICTOR AND DILATOR AGENTS IN VASCULAR BEDS WHICH DEMONSTRATE AUTOREGULATION. *In artificially perfused beds.* When studying responses to vasoconstrictor and vasodilator stimulation in a vascular bed which demonstrates autoregulation it may

be advantageous to use a constant-flow technique. This is particularly the case if the autoregulation is operating to maintain flow in proportion to metabolic need. Under these circumstances the change in arteriovenous difference of pressure probably will reflect the action of the infused agent with a minimum of complication. On the other hand, if constant pressure perfusion is used the autoregulatory mechanism may mask the effect of the vasoactive agent by providing a counterdilation or constriction in an attempt to maintain flow constant (see p. 940).

Interpretation of change of vasomotor tone in autoperfused vascular beds. Intravenous infusion of a constrictor agent which raises systemic arterial pressure may fail to alter blood flow in a vascular bed showing autoregulation. This lack of response may be interpreted incorrectly as indicating that the agent has exerted a vasoconstrictor effect. Such misinterpretation has been made in the case of the cerebral vascular bed. In such instances the vasoactive agent should be injected directly into the arterial supply to the vascular bed. If there should be no response to the intra-arterial injection then the lack of response during the rise of systemic arterial pressure with intravenous injection of the agent would be due to local autoregulation. In this case the vascular bed would be attempting to maintain flow constant despite the rise of arterial pressure (90b).

Chemical Effects on Resistance Vessels

Hypertonic solutions (above 5% NaCl) decrease the resistance to flow in systemic vascular beds (56)

by an unknown mechanism, but increase that in the lung. The latter seems to be due to intravascular red cell agglutination (91).

Potassium and magnesium ions cause active limb arteriolar dilation, calcium induces constriction (54) while sodium has little effect (86). Acetate, among the anions, produces arteriolar dilation (82).

Extrinsic Control of Resistance Vessels

EFFECTS OF VASOACTIVE AGENTS ON TOTAL RESISTANCE IN A VASCULAR BED. Extrinsic control of resistance vessels, i.e., of the peripheral resistance in the various vascular beds is illustrated most typically by the responses in a skeletal muscle vascular bed, since reactions, characteristic of all beds, are present in this bed. In a skeletal muscle bed, intra-arterial injections of epinephrine and of levarterenol cause a marked decrease in flow followed, often, by a secondary rise above control level (fig. 16). Such response occurs characteristically after all injections of levarterenol and after injections of 1 μ g or more of epinephrine. Smaller amounts of epinephrine often induce either no response or an increase in flow indicative of vasodilation. Lumbar sympathetic chain stimulation usually decreases flow (fig. 16), although occasionally an initial increase followed by decrease or solely an increase in flow occurs (30, 45, 117).

After induction of adrenergic blockade (fig. 16), levarterenol may have no effect or may cause a slight increase in flow while both epinephrine and lumbar sympathetic chain stimulation increase flow. Atropine injected intra-arterially abolishes the increase in flow

FIG. 16. Curves of arterial inflow in a skeletal muscle vascular bed in the dog in response to intra-arterial injections of 10 μ g of epinephrine, 10 μ g of levarterenol (norepinephrine), and a 1-min period of stimulation of the lumbar sympathetic chain, during a control period (left half) and after an intra-arterial injection of 0.3 mg/kg of phenoxybenzamine (right half). Flow measured in ml/min; arterial pressure remained constant through the study. [Modified after Youmans *et al.* (117).]

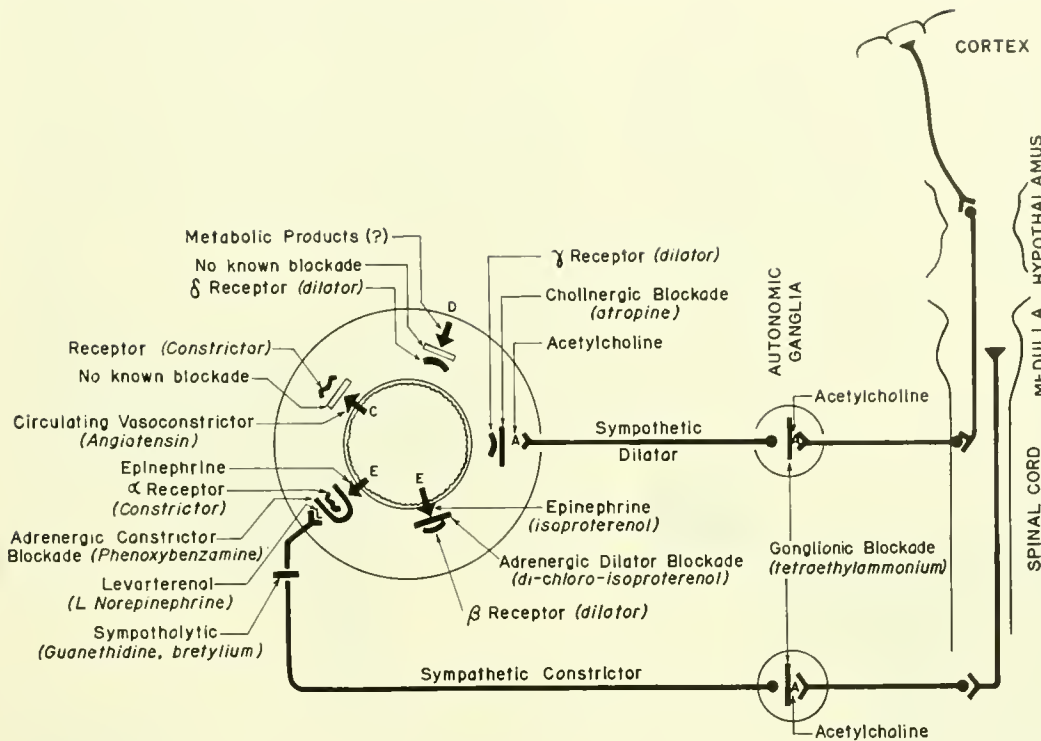

FIG. 17. Diagram of hypothetical receptor sites on arterioles in skeletal muscle. (See text for discussion.) [Modified from Green & Kepchar (45).]

induced by lumbar sympathetic chain stimulation, but has essentially no effect upon the dilator response to epinephrine (45, 90a, 117).

On the basis of detailed studies similar to the above, Ahlquist (1) proposed that two adrenergic receptors are present in blood vessels controlling the resistance to flow in vascular beds (fig. 17). The first of these has a constrictor (excitatory) action on vascular smooth muscle; but because it has an inhibitory action elsewhere (notably in the gut) it was not referred to as an excitatory receptor but, noncommittally, as the alpha receptor. It is blocked by phenoxybenzamine and similar adrenergic blocking agents. The second type of receptor causes relaxation of vascular smooth muscle but because it has an excitatory effect on the heart it was denoted as the beta receptor. It is blocked by dichloroisoproterenol. The alpha receptor is most sensitive to epinephrine, and least sensitive to isoproterenol, whereas the beta receptor is most sensitive to isoproterenol and least sensitive to arterenol.

We would prefer to limit the term alpha receptor to those receptors which are located on blood vessels. As such the alpha receptor would always be constrictor and innervated by sympathetic nerve fibers. We

would prefer also to limit the beta receptor to vascular sites. As such it would always be inhibitory (vasodilator) and to the best of our knowledge never innervated.

In addition to these two adrenergic receptors of Ahlquist, other vascular receptors have been proposed (45). A third group, the gamma dilator receptors, are excited by acetylcholine and by stimulation of sympathetic dilator fibers and blocked by cholinergic blocking agents such as atropine (45). A fourth possible group, the delta dilator receptors, may be excited by metabolic products or low tissue O_2 tension; they are probably the receptors which participate in autoregulation and reactive hyperemia. At present no agents are known which block the delta receptors. Several more receptors are probably present; those receptors, which respond to constrictor agents such as angiotensin, vasopressin, and similar polypeptides, are grouped together under the term "epsilon constrictor receptors"; no agents are known which can block these receptors.

The potency of various agents in inducing constriction or dilation varies from one vascular bed to another. Cerebral and cardiac vascular beds show essentially no constrictor response to adrenergic

agents, whereas all other beds show a significant response (fig. 18). Secondary dilation and the dilation following adrenergic blockade which occur with epinephrine are due probably to excitation of beta receptors; this effect is of significant magnitude in skeletal muscle bed and of lesser magnitude in cardiac, mesenteric arterial, and splenic vascular beds (fig. 19).

Sympathetic constrictor fibers exert maximal effects in kidney, skin, and mesenteric beds. Significant constriction is noted in muscle, spleen, and hepatic

FIG. 18. Bar graph of responses in various vascular beds to an intra-arterial injection of 1–10 μ g of epinephrine. Light-colored bars—initial responses; dark-colored bars—secondary (dilator) responses. See legend to fig. 12 for additional information. [Reproduced from (45).]

arterial and portal venous beds; but no significant reduction of flow occurs in cerebral or cardiac beds (fig. 20).

In the dog, unequivocal cholinergic dilator responses in response to sympathetic nerve stimulation are seen only in skeletal muscle (fig. 20) (45). However, Beck & Brody (4) believe that another active dilator pathway can be demonstrated in the dog's hind quarters perfused at a constant rate of flow. Dilation, primarily induced by this pathway, is most readily obtained by release of tracheal occlusion and is not blocked readily by atropine. It is claimed that in man there is a cutaneous vasodilator innervation (61, 94). It is claimed also that when sweat fibers are activated there is a release of bradykinin which causes secondary dilation in blood vessels adjacent to the sweat glands (34). However, Senay *et al.* (103) often found marked dissociation between sweating and vasodilation in the forearm.

SEGMENTAL RESISTANCES IN VASCULAR BEDS

Methods

The behavior of the small vessels, i.e., the arterioles and venules, may be inferred from comparison of the pressures recorded from fine catheters fed distally into small arteries and veins via the large vessels, with the lateral pressures recorded from the larger vessels (53, 57). Additional information is yielded when flows are measured simultaneously (14, 15). Micro-puncture studies have been used to obtain the pressures in the portal venous tree, portal venules, and central veins of the liver (83).

FIG. 19. Bar graphs of responses to intra-arterial injections of isoproterenol (B) compared with those to epinephrine during adrenergic blockade with phenoxybenzamine (Dibenzylene) (A). The ordinate values are the maximum flows in response to the agent, expressed as per cent of the control flow. The last bar (unshaded) represents the computed integrated effect on the total body flow (cardiac output). The sequence of the bars appears in the figure; the figures on the abscissa represent the per cent of cardiac output which flowed through the bed in the control period. See legend to fig. 12 for further explanation. [Reproduced from (45).]

Effects of Changes of Perfusion Pressure and of Venous Pressure on Large Artery and Vein, and Distal Small Vessel Pressures

In general, when perfusion pressure is varied while other factors remain constant, pressure in the small vessels parallels that in the large vessels (fig. 21).

FIG. 20. Bar graph of responses to stimulation of sympathetic constrictor nerve supply (A) and of sympathetic dilator nerves (B). The ordinate values give the flow at the moment of maximal response to the stimulation, expressed as per cent of the control flow. See legend to figs. 12 and 19 for further explanation. [Reproduced from (45).]

Elevation of an intestinal large vein outflow pressure leads to a progressive increase in the venous volume (yielding a measurable venous compliance), to a decrease in the venous resistance, to a progressive elevation of capillary pressure, and to a slower change in gut volume due to capillary filtration (67).

Effects of Extrinsic Agents on Segmental Resistance

Decrease in CO_2 tension and hydrogen ion concentration, produced by hyperventilation, induced dilation of the arteries with concomitant constriction of small vessels in intact forelegs. Opposite changes in both vessel segments were induced by increased CO_2 tension and hydrogen ion concentration. Serotonin decreased small artery pressure markedly associated with an increase in small vein pressure and no change in large artery and vein pressure or total resistance [Haddy (52)]. These findings suggest that serotonin exerts its effects predominantly on vessels larger than the arterioles and venules.

Intra-arterial infusion of epinephrine into the dog's paw caused the large artery to small vein pressure difference to increase as flow decreased (fig. 21C). Simultaneously, the small vein to large vein pressure difference decreased with flow in about the same degree as that which had been noted during control studies in which perfusion pressure had been lowered progressively (fig. 21A). Subsequently, large artery to small vein pressure difference decreased, and flow rose, but small vein to large vein pressure differ-

FIG. 21. Plots of relationship of blood flow in the dog's paw to pressure. A—flow vs. the difference between distal small vein and large vein pressure; B—flow vs. the large artery to large vein pressure difference; C—flow vs. large artery to distal small vein pressure. Heavy lines—successive responses to an intra-arterial infusion of 1 µg/min of epinephrine while the perfusion pressure was held constant at 200 mm Hg. Abscissal values for C = abscissal values for B minus abscissal values for A. Distal small vein pressures were recorded from an 0.5-mm polyethylene catheter inserted into a superficial vein and passed as far distally as it would go.

FIG. 22. Plots similar to those in fig. 21 showing the responses to an intra-arterial infusion of acetylcholine at the rate of 25 $\mu\text{g}/\text{min}$, 1; and to an intra-arterial infusion of acetylcholine at the rate of 100 $\mu\text{g}/\text{min}$, 2. Arterial pressure was held constant at 75 mm Hg for 1, at 105 mm Hg for 2.

ence increased. These findings suggest a dual effect of epinephrine, i.e., an initial small artery or arteriolar constriction, or both, and a subsequent small to intermediate vein constriction as the arterioles dilate [(55) and Rapela and Green, unpublished data]. Similar changes were recorded in dog's leg during sympathetic stimulation (13).

Acetylcholine, infused into a dog's paw, caused effects opposite from those of epinephrine. Small doses had no effect on the arterioles (fig. 22C, 1) but increased the small vein resistance (fig. 22A, 1); larger doses decreased the arteriolar resistance (fig. 22C, 2), but only slightly increased small vein resistance (fig. 22A, 2) [(52) and Rapela and Green, unpublished data].

Intermediate artery and vein behavior has been studied by inserting fine (0.5 mm) catheters centrally into a small artery and a small vein at the dog's ankle and recording the pressures during a control state and during strong stimulation of the peripheral homolateral lumbar sympathetic chain (15, 70). During stimulation pressure in the small artery fell dramatically while that in the small vein rose. These findings suggest a marked increase in the resistances to flow in the artery and vein between the points of cannulation and the more proximal points of pressure measurement in the larger arteries and veins. The stimulations were repeated as the catheters were fed into the artery or vein toward the knee (15). In the control state the arterial pressure was the same at all levels of the catheter tip but, during sympathetic

stimulation, a marked drop in pressure was noted in the artery at all points distal to 15 cm proximal to the ankle. These findings indicate that strong vasoconstriction occurred in the arterial tree midway between knee and ankle sufficient to stop flow and pulsations. Similar closures were recorded in the veins midway between knee and ankle. The morphological background for this was described by Shadle *et al.* (104); they noted that the dorsal foot veins were thick walled and difficult to distinguish from small arteries while veins from thigh muscles were thin walled.

In a subsequent paper, Davis & Hamilton (16) studied the responses further by a "cross-perfusion" method which allowed the blood to flow out of the proximal cut end of a small artery of the foot through a flowmeter and into the distal cut end of the corresponding artery of the opposite foot. Similar cross perfusion was arranged in the veins. Thus stimulation of the sympathetics on one side could affect flow only by causing constriction of the intermediate size vessels proximal to the ankle, whereas, stimulation of the sympathetic fibers on the opposite side of the body could affect flow only by causing constriction of small distal arteries, arterioles, venules, and small distal veins. They found that sciatic nerve stimulation produced intense constriction in both proximal intermediate and distal small arteries and veins which, in either case, was sufficient to stop flow. Lumbar sympathetic stimulation produced similar effects but they were slightly less intense in the paw than with

sciatic nerve stimulation. Incidentally, they noted that retrograde flow could be induced in the distal small vessels from vein to artery when these were not being stimulated, and the arterial pressure was low.

It should be noted that Davis and Hamilton speak of recording "small vessel" pressures, but it is our interpretation that the data indicate the role of intermediate vessels as well as arterioles and venules. It remains to be demonstrated whether the above observations represent a response that might occur under reasonable degrees of physiologic stress or a change that would occur only under unusual conditions such as intense electrical stimulation of the sympathetic chain. Effects such as these were significantly less marked in the intermediate vessels supplying the rabbit ear during stimulation of the third cervical nerve or the ipsilateral cervical sympathetic trunk (14).

BLOOD VOLUME IN VASCULAR BEDS (VASCULAR CAPACITY)

Methods

The volume of the various components of the vascular bed has been studied by injection techniques (77). The volume in a given vascular bed can be computed also by ligating abruptly the artery and vein, washing out the contained blood, measuring the hemoglobin content of the washout and comparing this with the hemoglobin content of the blood perfusing the bed.

Estimates of vascular capacity in an intact bed can be made by intra-arterial injection of an indicator with determination of the time course of the indicator concentration in the venous effluent (42). A typical record (fig. 23) shows an abrupt rise in the indicator concentration, beginning about 5 sec after the injection; the concentration reaches a peak in 10 sec and then returns to control level at approximately 90 sec. The rate of flow can be computed by dividing the milligram of indicator injected by the area under the indicator concentration curve, expressed in $\text{mg} \cdot \text{sec}/\text{ml}$ (fig. 23, *C* and *D*).

Curves *A* and *B* in figure 23 show the integration of the indicator concentration curve. By integrating the area above and to the left of the upper curve and dividing this area by the height of the curve, the mean transit time of the indicator through the vascular bed can be obtained. Multiplication of the mean transit time by the rate of flow gives the volume in the vascular bed. In this experiment on the paw, flow was 26.5 ml per min (0.44 ml sec), mean transit time 21.2 sec, and vascular volume 9.35 ml. Comparison of the flow measured with the indicator concentration curve with that measured simultaneously with the electromagnetic flowmeter shows the former to average 103 per cent (SD 4.6) of the latter. Correlation of the last determination of vascular volume with the vascular volume determined by the hemoglobin washout method shows that the former averaged 94 per cent (SD 38.5) of the latter (48).

Effects of Various Factors on Vascular Volume

In a set of experiments on the dog's paw, changes in perfusion pressure produced approximately proportional changes in flow (fig. 24), whereas mean transit time varied inversely. As a consequence neither vascular volume nor conductance ($1/\text{resistance}$) was altered to any significant extent. Acetylcholine,

FIG. 23. Records obtained from the dog's paw showing the time course of the concentration of an indicator (indocyanine green) recorded in the venous outflow following an intra-arterial injection of the indicator. *C*, *A*: curve recorded from the output of an integrator whose input was the output from the indicator concentration recorder. Time lines at the top—5 sec. *B* and *D*: similar records obtained during an intra-arterial infusion of acetylcholine, which were recorded after a stable rate of flow had been attained. Perfusion pressure 116 mm Hg for all four curves. In each case, 0.125 mg of indicator was injected as a square-wave pulse during a 1-sec period. The upper asymptote was drawn parallel to "integrator base line." The slight inclination of the latter was due to a failure to balance the integrator to the densitometer output when control blood was flowing through the cuvette. A 2- to 3-sec delay is noted between the beginning movement of the densitometer and the beginning movement of the integrator pens. This is due in part to the lag of the recorder and possibly to slight delay in the integrator. It is corrected in the calculations since the true mean transit time is obtained by subtracting the delay time from the apparent mean transit time. The delay time is obtained by making a second injection at the sampling site in the venous outflow.

FIG. 24. Effects of perfusion pressure per se (circles) and of an infusion of acetylcholine at each level of perfusion pressure (triangles) on flow, mean transit time, volume, and conductance in the dog's paw. Same experiment as that in fig. 23. *A*: plot of perfusion pressure (arteriovenous difference of pressure) vs. flow. [In a larger series of experiments the pressure-flow relationship in the vascular bed of the paw was best represented by a curve with convexity towards the pressure axis, when plotted in linear coordinates, similar to that observed in the skin (fig. 3)]. *B*: plot of perfusion pressure vs. mean transit time. *C*: plot of perfusion pressure vs. vascular volume (computed from product of flow \times mean transit time). *D*: plot of conductance vs. vascular volume. Figures in *D* represent the perfusion pressures used for each pair of determinations.

infused intra-arterially in this experiment had similar effects at all levels of perfusion pressure. This agent increased flow and, thereby, lowered the amplitude of the indicator concentration curve (fig. 23). However, mean transit time did not change appreciably and therefore vascular volume and conductance were both increased, the latter proportionately more than the former (fig. 24). The straight-line relationship between flow and pressure may indicate a considerable though not maximal dilation of the arterioles (p. 937).

When using indicators it is necessary that a stable state exist since, if the volume is changing during the determination, a false reading will be obtained. When this occurs, the flow computed by the indicator method may differ significantly from that recorded simultaneously by a flowmeter.

ESTIMATION OF CHANGE OF VASCULAR VOLUME DUE TO EXTRINSIC INFLUENCES

Changes in vascular volume in an organ may be measured by recording continuously the organ's weight or its volume with a plethysmograph. These methods give the relative change of vascular volume but not the actual volume of blood in the bed at any moment. Changes in vascular volume measured by these methods may be used to confirm changes in volume obtained with the indicator method. Comparison of change of vascular volume with simultaneously recorded blood flow gives an indication of the interplay of resistance and capacitance vessels (31, 80).

Different vascular beds vary significantly in their response to factors causing a change of vascular

volume. In response to intra-arterial epinephrine the vascular volume in the dog's paw tends to decrease as the resistance to flow increases, i.e., as flow decreases.

During constant-flow perfusion of the isolated dog's hind quarters intra-arterial perfusion of levarterenol caused *a*) a marked rise in the perfusion artery pressure (increased resistance to inflow through the arterioles); *b*) a decreased venous outflow; and *c*) a rise in limb weight (due to distention of the arteries proximal to the site of constriction). When the rising arterial pressure overcame the arteriolar resistance outflow increased above inflow and limb weight fell despite persistence of the elevated arterial pressure. The authors concluded that the latter effect was due to translocation of blood by constriction of the veins. Because of the small changes of T-1824 and P³² tag concentrations, they concluded also that only a very small percentage of the leg weight change was due to transcapillary movement of either plasma or interstitial water (104).

Reductions in flow and volume were noted in cat's hind legs in response to levarterenol; this finding was interpreted as being due to constriction of both the "resistance" and the "capacitance section" of the vascular bed (31, 80). In this preparation intra-arterial epinephrine caused an initial increase in outflow simultaneously with a decrease in volume, whereas isoproterenol and acetylcholine increased both flow and volume. Since levarterenol seemed to be more potent than angiotensin in reducing the volume of blood contained in the capacitance section of the hind leg (muscle and skin) of cats, Folkow *et al.* (33) claimed that a greater constrictor effect on

the capacitance vessel (larger veins) is exerted by levarterenol than by angiotensin. As we visualize it, the data should be interpreted oppositely, i.e., that angiotensin has a more potent effect than does levarterenol on the postcapillary, or a less potent effect on the precapillary vessels (see below).

The vascular volume of the spleen decreased more rapidly and abruptly than the inflow in response to intra-arterial epinephrine, levarterenol, or sympathetic nerve stimulation. After a period of time the inflow began to increase rapidly exceeding outflow and resulting in a progressive augmentation of spleen weight (47) (fig. 25).

The usual accompaniment of an increase in vascular resistance of an organ is a decrease in its volume as measured plethysmographically or by weight changes. This change is the result of a diminution of the volume of the resistance vessels (arteriolar constriction) and perhaps more importantly the lessening of the distention of the postarteriolar vessels and even the closure of some of the capillaries and venules (fig. 26). Only rarely is an increase in resistance accompanied by an increase in organ volume. When this occurs, it is due probably to a preponderance in the resistance increase of postcapillary or even venular vessels over that occurring in the precapillary vessels, thus causing an increase in upstream (capillary) pressure which may lead to an augmentation of organ volume by distending the capillaries (fig. 26) and by increasing the filtration of fluid into extravascular spaces. The kidney is the only organ in which a well-documented increase in volume accompanies an increase in resistance. That this is due in part to an increase in

FIG. 25. Records of arterial inflow, venous outflow, and relative weight changes of the dog's spleen in response to stimulation of sympathetic nerve supply and of the dog's paw in response to slow intra-arterial infusion of 1 μ g/min of epinephrine. [Modified after Green *et al.* (47).]

intravascular volume rather than an increase in extravascular volume (106) has been shown by Mehrizi and Hamilton (79) using calculations from mean transit time. It has been attributed classically to constriction of efferent glomerular arterioles and a passive distention of upstream vessels.

In short, changes in vascular volume as a result of increased resistance to flow can be attributed to any combination of three causes, all operating at the same time: 1) decreased volume of constricting vessels, 2) decreased distention of downstream vessels, and 3) increased distention of vessels upstream to the site of preponderant increase in resistance. The net change in vascular volume will, then, depend on the location

of the resistance increase in the morphological pattern of the vascular network. A lessening of resistance in any part of the network will presumably induce opposite changes in vascular volume. These structures are affected differentially by various vasoactive agents. Data are insufficient at present to draw significant generalizations regarding the various vascular beds.

PULSATILE CHANGES IN VASCULAR VOLUME

Pulsatile flow through a dog's ulnar artery was measured with a square wave electromagnetic flowmeter together with pressure recorded in a small branch just proximal to the flowmeter and with paw volume pulse recorded plethysmographically (fig. 27). The flow record showed a dicrotic notch but never fell to or below zero during diastole. A volume pulse calculated by integrating the flow pulse and subtracting an assumed constant venous output was essentially similar (fig. 27). Both showed two humps of approximately similar magnitude.

In man, the normal digital volume pulse rises relatively more rapidly than that of the dog's paw, has a sharp peak at the end of the first quarter of the pulse interval, and a slight notch about halfway down the descending limb (fig. 28). If the supplying artery is occluded but adequate collateral circulation is available, the digital pulse shows a peak which is rounded and delayed, and the notch on the descending limb is absent. In the presence of vasospastic disease, the peak may be delayed slightly, the notch raised or may occur sooner on the descending limb, and the area of pulse per unit amplitude increased in comparison with the normal. With elevation of venous pressure or interference with venous outflow, the peak of the pulse is sharper than normal and a second hump

FIG. 26. Hypothetical plots of the pressure drops in various portions of the terminal vascular bed during a control state, solid line; during a state of increased precapillary resistance, dash-dot line; and increased postcapillary resistance, dashed line.

FIG. 27. Records of A—pulsatile arterial inflow; B—pulsatile arterial pressure; and C—pulsatile plethysmographic volume, in the dog's paw. Arterial inflow recorded with an electromagnetic meter on the ulnar artery. D—pulsatile volume calculated from the pulsatile arterial inflow, assuming a constant venous outflow.

FIG. 28. Averaged plethysmographic pulses from the digits of patients. *A*—normals; *B*—patients with arterial occlusion, but with good collateral circulation; *C*—patients with vasospasm; *D*—patients with deep thrombophlebitis. All pulses are redrawn to the same amplitude and same time duration. Note: the flow to pulse ratios in the patients with arterial occlusion were 2 to 5 times those of the normals.

follows the notch, indicating a larger than normal reflected wave component in the volume pulse (11).

INTERPRETATION OF VASCULAR BEHAVIOR FROM MEASUREMENTS OF FLOW, PRESSURE, AND VASCULAR VOLUME

Flow through a vascular bed is dependent upon arterial pressure, arteriolar inflow and venous outflow resistances, viscosity of the blood, and extravascular pressure. Physiologic control of flow is exerted in many vascular beds by local autoregulation as modified by the influence of autonomic nerves and by circulating constrictor substances.

Analysis of the influences of autonomic nerves and circulating vasoactive substances under conditions of various physiological stresses is complicated, particularly if there is an accompanying change of arterial pressure. For instance, if there is a decrease in arterial pressure to 50 per cent of the control, the measured

peripheral resistance might increase in a nonreactive bed such as the skin, whereas the resistance might decrease in a reactive bed such as that of kidney, brain, or skeletal muscle. These changes would occur in the absence of extrinsic influence. Therefore, in order to analyze the potency of extrinsic influences upon the resistance vessels, it is necessary to obtain previous data on the behavior of the resistance vessels during changes of pressure per se in the absence of extrinsic influences, and then compare the measured changes in resistance with these pre-established findings before drawing any conclusions as to the influence of extrinsic factors on the vascular bed.

Similar observations apply to measurements of vascular volume. The latter measurements become important, particularly in conditions such as shock in which it is presumed that there is a stagnation and pooling of blood in various vascular beds; however, extensive data are not as yet available on such changes in vascular volume.

Nonuniform Distribution of Blood Flow in Relation to Blood-Tissue Exchange

I. FILTRATION AND ABSORPTION; GENERAL FORMULATION

"TRANSUDATION OF WATER AND SOLIDS" through the walls of blood vessels was proposed by Bartholin (10) in 1653 to explain the flow of lymph. This suggestion was largely neglected though a somewhat similar process was expressed vaguely by Hales (140) in 1753 as an "insinuation of liquid" into the wall of the intestine in connection with some of his more prolonged perfusion experiments. Ludwig (223) proposed a definite filtration theory in 1861 based largely upon observations made by Noll (263)

¹ Career Investigator, American Heart Association.

in his laboratory in 1850. According to Ludwig: "... the blood which is contained in the vessel tends to equalize, through the porous vessel walls, its pressure and its chemical composition with those of the fluids which lie outside the vessels. If, for example, the contents of the vessels increases, the pressure in the vessels also increases, and immediately a portion of blood passes out into the tissues, driven by a filtration pressure."

But this "filtration pressure" proved unable, by itself, to explain either the control of the volume of lymph flow or the regulation of the constancy of blood volume. Many of Ludwig's earlier experiments supported his belief that this was accomplished by a direct relationship between blood pressure, filtration, and lymph formation, followed by return of this lymph to the blood stream. Elevating venous pressure in portions of the circulation of a whole animal increased lymph flow, as did also elevating arterial pressure in perfused tissues. However, others showed very soon that elevations of blood pressure produced by vasomotor changes did not always produce the predicted increase of filtration. Moreover, little lymph could be obtained from the resting limb; whereas Ludwig's filtration hypothesis required that even resting blood pressure should have produced both filtration and lymph flow.

The problem became temporarily still more obscure after 1880 when Heidenhain began studying the abundant flow of lymph from the thoracic duct which continued even during rest. The actions of his two classes of lymphagogues, coupled with slight but definite inequalities of solute concentrations in plasma and lymph (explained now, in large part, by the Gibbs-Donnan equilibrium) led him to postulate active secretion by the cells of the capillary walls and possibly by the lymphatics (145a). Heidenhain found Ludwig's simple filtration theory adequate for some conditions and quite unable to explain others. On the other hand, Heidenhain's secretion theory was supported by no direct proof. At this point Starling measured the osmotic pressure of the plasma proteins and added absorption to Ludwig's filtration. In 1896, under the title "On the absorption of fluids from the connective tissue spaces," Starling wrote:

"... although the osmotic pressure of the proteids of the plasma is so insignificant, it is of an order of magnitude comparable to that of the capillary pressures; and whereas capillary pressure determines transudation, the osmotic pressure of the proteids of the serum determines absorption." (345)

This hypothesis, despite its attractiveness, did not

find general acceptance for several decades until improved methods were developed for measuring the osmotic pressure of the plasma proteins and also capillary blood pressure. Apparent exceptions to the hypothesis became explicable as investigators learned more about the nature of the capillary wall itself, the hydrostatic pressure of the interstitial fluid, and the osmotic pressure of the proteins in that fluid.

For purposes of summary, and of consecutive, more detailed discussions of each factor, a general relationship can be formulated. It must be emphasized, however, that this formulation is a composite which is based on many overlapping experiments, each of which dealt simultaneously with several of the variables, but not with all.

$$F.M. = k(P_c - \Pi_{pl} - P_{if} + \Pi_{if}) \quad (1.)$$

+ = filtration
- = absorption

F.M. represents fluid movement through the capillary wall, with a plus sign to indicate filtration, and a minus sign to indicate absorption. P_c is capillary blood pressure (hydrostatic); Π_{pl} , the osmotic pressure of the plasma proteins; P_{if} , the pressure in the interstitial fluid compartment (hydrostatic); and Π_{if} , the osmotic pressure of the proteins in the interstitial fluid immediately outside the capillary walls. The proportionality factor, k , has been called a filtration constant or, more appropriately, a filtration coefficient and is a measure of the permeability of the capillary wall to isotonic fluid. Each of these factors will be considered in succession.

2. CAPILLARY BLOOD PRESSURE, P_c

A. Methods of Measurement

The pressure under which blood flows through the capillary vessels was very much in the minds of the earliest investigators even when pressure measurements were limited to large blood vessels and to lower animals. Thus Hales, in 1773, having determined the first arterial and venous pressures, went on at once to make certain assumptions and then calculated the "force of the blood in the capillary vessels" to be 1.838 gr. with the qualification that to this "must be added the velocity which the blood has acquired at its first entrance in the capillary vessel, which can be but small as appeared by the great resistance it meets within the capillary vessels..." (140). In 1828 Poiseuille (286) devised the U-tube mercury manometer and measured the gradient of pressure

in the arterial system. With smaller and smaller cannulae he measured pressures in the aorta, carotid artery, and even in a 2-mm branch of the crural artery, and reported: "that a molecule of blood moved with the same force throughout the course of the arterial system, which a priori, with all physiologists, we were far from thinking." It followed, therefore, that the major fall of blood pressure must occur somewhere in the smaller vessels beyond the ones he cannulated. Poiseuille then turned his attention to capillary tubes and studied the relation which volume flow of liquids per unit time bears to pressure, viscosity, tube radius, tube length, and wall surface (287-289). Hence Poiseuille's equation, which underlies the science of hydrodynamics, emerged from questions concerning arterial and capillary blood pressure in animals.

In 1875 von Kries (182) tried to measure capillary blood pressure in man by an indirect method. He placed a glass plate, 2 to 5 mm² in area, on the skin and hung from this plate a small scale pan on which weights were placed until the skin blanched. Five years later Roy & Brown (309) used a capsule fitted with a distensible, transparent membrane to determine, under the microscope, the pressures required to modify or obstruct flows through single arterioles, capillaries, and venules in the more or less transparent tissues of experimental animals, e.g., the web of the frog. From 1886 to the present, various modifications of these two basic methods were used for many measurements but yielded discordant results, ranging even in one species, man, and in one tissue, skin, from 1 to 71 mm Hg (207). Most of these studies were made after 1900 because figures for capillary blood pressure were necessary to prove or disprove Starling's filtration-absorption hypothesis. Even as late as 1925 no conclusions could be reached because the lower values were less than venous pressure and obviously questionable.

The higher values were criticized because they were based on blanching of the skin or on arrest of blood flow by microscopic examination, and so indicated arteriolar rather than capillary pressure. Moreover, no indirect method could yield information concerning the presence or absence of a gradient of pressure in the capillary network itself. When reviewed in 1934 (207) indirect methods were found inadequate *a)* because of variable transmission of pressure through overlying tissues to the capillaries beneath, and *b)* because of the arbitrary and unproved criteria adopted by various investigators to indicate when externally applied pressure equaled the pressure

within the capillaries. Direct measurements of the sort attempted by Poiseuille a century earlier were still necessary.

The requirements for direct measurements of pressure in single capillaries are basically simple, though technically somewhat difficult (198, 203). Figure 2.1 shows (upper left) a micropipette, 5 μ in diameter at its tip, under the microscope and ready for use. A somewhat smaller pipette (lower left) is shown inserted into a capillary of the frog's mesentery. The micropipettes are first carefully filled with a saline solution containing heparin, mounted in a micromanipulator and connected to a manometer and syringe (right) so that the pressure exerted on the saline at the tip of the micropipette can be changed rapidly and accurately to balance the changing pressure in the capillary. The micromanipulator is required not only to insert the pipette into the capillary, but also to keep the lumen of the pipette in free communication with the lumen of the capillary. Minute rods (fig. 2.1, upper left), each controlled by its own micromanipulator, are frequently necessary in addition to hold steady thin tissues such as mesentery. Pressure readings from the manometer can be made only at true pressure equilibrium without net flow of liquid through the tip of the pipette because orifices of 5 to 10 μ interpose considerable resistance to flow and consequent inaccuracies. Failure to observe this precaution has yielded fallaciously low values for capillary pressure (36, 203).

With these requirements in mind, suitable criteria were developed for measuring mean, systolic, and diastolic pressures in single capillaries, arterioles, or venules in mesentery (198), skin (205), and muscle of lower animals as well as in the skin of man (203) with an accuracy of a few millimeters of water. Tests showed that changes of capillary pressure induced by graded venous congestion could be detected promptly and accurately by the direct method (203) but not by an indirect method (88).

B. Capillary Pressures in Various Tissues; Relation to the Osmotic Pressure of the Plasma Proteins

Direct measurements of pressures in single capillaries, arterioles, and venules provided answers to Poiseuille's questions concerning the nature and the location of the pressure gradient in the circulatory system. Figure 2.2 shows that in the mesenteric blood vessels of the frog, the major decrease of pressure (70 to 80%) occurred in the arterioles, but there

FIG. 2.1. Diagram of apparatus for measuring capillary blood pressure directly. Micro-pipette shown before introduction (*upper left*) and in capillary after introduction (*lower left*). [From Landis (198).]

FIG. 2.2. Curve showing average gradient of pressure through the mesenteric blood vessels of the frog. [From Landis (198).]

was also a significant drop in the capillaries, amounting on the average, with ordinary blood flows, to 20 or 30 per cent of the total (198). A somewhat smaller gradient was also calculated from Poiseuille's equa-

tion and motion picture analyses of flow through capillary networks (206).

The same determinations provided direct support for the Starling filtration-absorption hypothesis.

TABLE 2.1. *Resting Average Capillary Blood Pressure (P_c)* and Osmotic Pressure of Plasma Proteins (Π_{pl})*

| Animal | Π_{pl} | Average P_c | | Tissue (and Reference for P_c) |
|-----------------|------------|----------------|------------|-----------------------------------|
| | | Arteriolar end | Venous end | |
| | mm Hg | mm Hg | mm Hg | |
| Frog | 5-10 | 10.6 | 7.4 | Mesentery (198) |
| | | 11.0 | 7.0 | Muscle (205) |
| | | 10.7 | 7.4 | Skin (205) |
| Rat | 16-21 | 22.1 | 12.5 | Mesentery (202) |
| Guinea pig | 17-21 | 28.3 | 12.5 | Mesentery (202) |

* Direct measurements only. † Summit of the capillary loop.

In the arteriolar end of the frog's mesenteric capillary network pressure averaged 14.5 cm H₂O or 10.6 mm Hg; in the venous end about 10 cm H₂O or 7 mm Hg. Since the osmotic pressure of the plasma proteins ranged in normal frogs from 5 to 10 mm Hg (41), the approximate balance predicated by Starling was present except when starvation, as in winter frogs, reduced the concentration of plasma proteins (23, 41). As shown in table 2.1, capillary blood pressures in frog's muscle and skin were similar to those in the mesentery (205). In the mesenteries of rats and guinea pigs a balance was also found but at a higher level of pressure (202). Pressures were highest in the intestinal capillaries of the cat (178) and in the cutaneous capillaries of man (89, 92, 203, 225), but again in balance with the higher osmotic pressure of the plasma proteins as shown in figure 2.3. Thus in four tissues and in five species the pressures found were generally compatible with Starling's view that, on the average and at resting blood flows, these pressures favor filtration in the arteriolar portion of the capillary network and a balancing absorption in the venous end of the capillary network. But generalizations cannot be extended to tissues with specialized functions. Capillary blood pressures may be higher in kidney and lower in lung.

Hayman (145) found that glomerular capillary

pressure in the frog averaged 54 per cent of the simultaneously measured aortic blood pressure. White (377) observed pressures of similar magnitude in *Necturus*. For mammalian glomeruli direct measurements are lacking, but indirect estimates have ranged from two-thirds of arterial pressure by Winton (384) to about 50 per cent of arterial pressure by Gottschalk & Mylle (124). The high rate of glomerular filtration can be explained by these high capillary pressures and the greater effective pore area of the glomerular membranes (278). The mechanism by which 98 per cent or more of this filtrate passes back into the blood of the peritubular capillaries cannot be explained so simply.

Postglomerular or peritubular capillary pressures have been measured directly by Wirz (385) who reported 17.4 ± 2.6 mm Hg for a small series of rats and by Gottschalk & Mylle (124) who found averages of 20.4 and 14.2 mm Hg for large and small peritubular capillaries, respectively, under normal conditions. These pressures increased, however, to very high levels not only during venous

FIG. 2.3. Curves comparing gradient of pressure drop (open circles) in four species with the corresponding osmotic pressures (filled circles) of their plasma proteins. [Modified from Landis (207).]

congestion, but also after dextrose infusions, e.g., to 37 mm Hg, and during ureteral occlusion, e.g., to 40 mm Hg, with relatively close parallelism between intratubular, interstitial, and peritubular capillary pressures. Evidently, the hydrostatic pressure difference across the walls of renal peritubular capillaries is far less than across the walls of peripheral capillaries generally. This implies that the full osmotic force of the plasma proteins, unopposed by hydrostatic pressure differences, may be available for withdrawal of tubular reabsorbate from renal interstitial fluid to blood.

Pulmonary capillary pressure presents an exception in the opposite direction. Though direct measurements are not available as yet, an indirect "wedging" method (146, 147) has made it clear that in the lung capillary pressure is normally between 5 and 15 mm Hg in dog and man and is, therefore, well below the osmotic pressure of the plasma proteins. Absorption is favored (55) and ensures a minimum of interstitial fluid in the alveolar walls, which is an important consideration in a tissue the prime function of which is to permit rapid exchange of gases. In normal subjects these "wedge pressures" are quite constant; exercise produces elevations of not more than 3 or 4 mm Hg. Greater elevations than this during exercise have been found to be helpful in detecting early left ventricular failure or slight mitral stenosis not yet severe enough to produce clinical symptoms or signs (291).

Retinal capillary pressure has not been measured directly, but must be considerably higher than that in muscle or skin in order to maintain blood flow despite an intraocular pressure of about 20 mm Hg. Nor are any reliable figures available for capillary pressures in other special regions, e.g., brain, pleural and peritoneal surfaces, joints, etc. In view of the differences between capillary pressures in skin, kidney, and lung, generalizations are obviously unjustified and direct measurements are needed for each tissue.

C. Variability of Capillary Blood Pressures Under Control Conditions

The average figures so far given would, by themselves, present an erroneous idea of the potential role of capillary pressure in the filtration and absorption of fluid. In any one tissue capillary pressure, like the more easily observed capillary blood flow, varies from moment to moment and from capillary to capillary even when they arise from the same

arteriole. This is to be expected from the responsiveness of the terminal arterioles and arteriocapillary sphincters to nerve impulses, both constrictor and dilator, to local metabolic products and also to mild injury such as that produced by manipulation, exposure to air, and cannulation itself (198, 203, 205). In the skin of frog (205) and man (203) the mere introduction of a minute pipette sometimes produces a brief rise of capillary pressure accompanying the transient vasodilatation of a "triple response" to injury.

It must also be emphasized that capillary pressure has been measured directly in relatively few tissues. In man, determinations have been limited to the capillary loops in the nailfold where arteriovenous anastomoses are also present and may influence pressure measurements. As shown in table 2.1, in one series pressure in the arteriolar loops averaged 32 mm Hg. However, the single readings ranged from 21 to 48 mm Hg; in the venous loops the corresponding figures were 12 and from 6 to 18 (203). In another series of control measurements Eichna & Bordley (89) found even larger variations, much more overlapping of values, and a smaller average gradient, viz. 31 to 22 mm Hg rather than 32 to 12 (table 2.1). These differences may possibly be related to room temperature because the larger gradient and lower pressures in the venous limbs of the capillaries were found at room temperatures of 18 to 20 C (203). The smaller gradient and higher venous capillary pressures were observed in a warm room where temperatures were 23 to 28 C (89). It seems likely that capillary pressures in human digital skin, particularly in the venous limbs next to the subpapillary venous plexus, can be influenced by the state of the arteriovenous anastomoses. At higher room temperatures opening of these large channels, and increased blood flow direct from larger arterioles to larger venules, may well increase pressure locally in the subpapillary plexus into which the true capillaries also discharge their blood.

Chambers & Zweifach (37) have suggested, in addition, a division of function in the minute vessels, viz. that higher pressures, and hence filtration, may occur chiefly in the direct, arteriovenous channels, with lower pressures and absorption located in the true capillaries. For such specialization, however, no supporting evidence in the form of pressure measurements in direct channels is available. Moreover, very high pressures and filtration rates were frequently found in true capillaries (200). Zweifach (387) also suggested that "the arrangement whereby

the true capillaries come off at right angles to the A-V vessels favors the development of 'suction forces,' especially where a rapid, continuous flow courses only through the A-V channels." No suction forces were encountered in any of the many direct measurements of capillary pressure. The reason for this becomes clear in considering actual rather than apparent velocities of flow in the minute vessels. Under the microscope, which magnifies linear velocity as well as size, flows that seem very rapid indeed are really between 1 and 2 mm per sec. Calculation of the magnitude of the corresponding velocity effect by the Bernoulli equation shows the insignificance of any possible suction force, viz. for a linear velocity of 2 mm per sec a pressure difference of only .000015 mm Hg.

Far more important is the conspicuous variability of pressures found throughout the entire minute vessel system as shown in figure 2.4 for the exposed frog's mesentery where measurements could include larger vessels as well as capillaries. In general, high capillary pressures were associated with very rapid flows (if venous outflow was normally free) and with increased pulse pressure in the capillary network. Lower pressures, approaching venous pressure, were associated with slower flow or absence of flow (198). Hence, as arteriolar diameter or tone of precapillary sphincters changes from moment to moment, even under resting or control conditions, the average balance between highly variable capillary pressures and the much less variable osmotic pressure of the plasma proteins often includes temporary imbalances in single capillaries and corresponding shifts toward periods of filtration or absorption. McMaster (235) has suggested that such shifts ex-

plain, in part, the intermittent entry of Locke's solution at atmospheric pressure into the skin through a fine needle introduced carefully to avoid both blood vessels and lymphatics.

Position of a capillary bed, relative to the heart, affects capillary blood pressure in general accordance with changes of hydrostatic pressure (203). In the finger tip of man at heart level average pressure in the arteriolar portion of the capillary loop was 32 mm Hg and in the venous portion 12 mm Hg, with large individual variations in single capillaries around these averages. When the hand was 30 cm above heart level these average pressures became 23 and 10 mm Hg, respectively, further drop being arrested presumably because of collapse of the thin-walled veins in the arm. Conversely, lowering the forearm to 40 cm below heart level increased average arteriolar and venous capillary pressure to 45 and 33 mm Hg, respectively.

The relation between capillary blood pressure and the osmotic pressure of the plasma proteins is therefore extremely labile, both as to time and the area of capillary wall involved. Absorption may be favored in a large segment of the capillary bed for considerable periods, e.g., during vasoconstriction or elevation of an extremity and filtration favored for other periods, e.g., during vasodilatation or dependency. Nevertheless, a net equilibrium is maintained and favors constancy of plasma volume and interstitial fluid volume. Under exceptional conditions, e.g., muscular activity, prolonged dependency of an extremity, high temperature, injury, and inflammation, excessive capillary filtrate must be returned to the blood stream by the lymphatic vessels. These ancillary vessels, as described in the following section,

FIG. 2.4. Chart showing variability of capillary blood pressure and of pressure gradient in the blood vessels of the frog's mesentery. The higher capillary pressures and increased capillary pulse pressure are characteristic of vasodilatation. The lower capillary pressures and absence of measurable pulse pressure are characteristic of vasoconstriction. [From Landis (198).]

provide an important safeguard against abnormal accumulations of capillary filtrate in the interstitial fluid compartment.

D. Functional Changes of Capillary Blood Pressure

Hemorrhage and local application of epinephrine produced vasoconstriction in the frog's mesentery and reduced capillary blood pressure as shown in the lowermost curves of figure 2.4 (198). In man the marked vasoconstriction and cessation of blood flow found in Raynaud's disease reduced capillary blood pressure in the affected digits to between 5 and 8 mm Hg, i.e., to levels approaching local venous pressure (204). During the hyperemia of recovery, pressures in these same capillary loops rose rapidly to between 32 and 45 mm Hg. In normal subjects, however, local cooling and vasoconstriction reduced capillary blood pressure only moderately and the rise of pressure during the secondary hyperemia of cold was likewise moderate (203). Also in man Eichna & Wilkins (90) found that neurogenically induced vasoconstriction reduced cutaneous capillary pressure by 1 to 8 mm Hg in 52 of 89 observations with no change or slight elevations of 1 or 2 mm Hg in the remainder. Intravenous injection of 1 or 2 μ g of epinephrine reduced capillary pressure by 1.5 to 22 mm Hg in seven of ten experiments but in three subjects elevations of 1 or 2 mm Hg were observed. Sympathectomy obliterated neurogenic effects, but not those of epinephrine. In the vasoconstriction of human hypertension capillary pressure was not significantly elevated and minor increases found in some subjects were independent of arterial pressure (89); this was also true of the temporary rise of arterial pressure produced by Paredrinol intravenously (87) with or without prior sympathectomy.

Conversely, vasodilatation increased capillary blood pressure, frequently to very high levels approaching arteriolar pressure (see fig. 2.4). Capillary pressure also rose during local vasodilatation induced in the frog by dilute urethan (198), by injuries which produced hyperemia and capillary stasis (199), by a simple triple response and after muscular contraction (205). In human skin the hyperemias of local heating, intradermal histamine, inflammation, and reactive hyperemia after cold (203) were accompanied by elevations of capillary pressure to maxima between 49 and 60 mm Hg. In these observations room temperatures were low, 18 to 20 C. At higher temperatures, 23 to 28 C, Eichna & Bordley (89) found that intradermal histamine

elevated capillary pressures much less conspicuously and more in the venous than in the arteriolar limbs in both normal and hypertensive subjects. It was emphasized that arteriovenous anastomoses may have been involved in these effects (203).

From the higher capillary pressures found in localized vasodilatation and hyperemia it might be thought that excessive filtration and increased lymph flow must occur with any vasodilatation. This is not always the case, however. The most notable exception is the repeated finding that denervation of an extremity produces hyperemia and evidence of increased blood flow without change of lymph flow, or at most a very slight increase, as reviewed by Drinker & Field (76). This failure of widespread vasodilatation to increase the flow of lymph was, in fact, for many years cited as evidence against the Starling hypothesis. Eichna & Bordley (89) found that reactive hyperemia and also indirect or reflex vasodilatation in man, produced by body warming, did not increase cutaneous capillary pressure significantly. The reason for this may lie in the lowering of pressures in the digital arteries by 10 to 40 mm Hg during the generalized vasodilatation produced by body warming (73, 114, 115, 244), by exercising the forearm muscles (73), or by reactive hyperemia (365). The named arteries to an extremity are apparently large enough to conduct blood at resting flow rates with little pressure drop. The lesser increments of flow required by localized vasodilatation are associated with little drop in arterial pressure and capillary pressure rises conspicuously. However, when vasodilatation involves the resistance vessels of a whole extremity, and blood flow through the large arteries is increased severalfold, the pressure drop from brachial artery to digital artery becomes significant. Then, arterial pressure head being much reduced locally, the rise of capillary pressure is limited even with maximal arteriolar dilatation. In addition, the capillaries lie between two resistances and it is quite possible that arteriolar dilatation will not raise capillary pressure if the venules and veins are simultaneously dilated in similar or greater proportion.

E. Effects of Venous Pressures and of Venular Constriction on Capillary Pressure

Elevations of venous pressure produce, as might be expected, a rapid increase of capillary pressure to levels above the pressure in the veins. Direct measurements have shown this to be true of localized

obstruction of a venule in the frog's mesentery (198) and also when the human extremity was congested by inflating a cuff previously placed on the upper arm (88, 203). When blood flow was normal, capillary pressure equalled cuff (and venous) pressure within 15 to 45 sec and eventually exceeded cuff (and venous) pressure by 8 to 14 mm Hg in the 2nd to 4th minute of congestion (203). When blood flow was very slow, however, as in the arteriolar constriction of acrocyanosis (220), capillary pressure rose much more slowly, requiring up to 8 min to equal venous pressure and finally exceeding that pressure by only 1 or 2 mm Hg. Other direct measurements have shown that capillary pressure is elevated in congestive heart failure (92) and also in glomerulonephritis (225) whenever venous pressure is high, returning to normal as venous pressure declines. In all these measurements the variability of normal, resting capillary pressures prevents making any meaningful comparison of the increment of capillary pressure which corresponds to any given increment of venous pressure.

The effect of venous pressure on capillary pressure was emphasized in 1894 on the basis of indirect evidence by Bayliss & Starling (12) when they observed that elevating venous pressure increased lymph flow more than similar changes of arterial pressure. In the absence of a direct method of measuring capillary pressure they suggested using changes of venous pressure to deduce changes of capillary blood pressure. Also, from studies of lymph formation, Drinker & Field (76) in 1933 suggested that, other things remaining constant, the state of the veins might modify capillary pressure and thereby influence filtration of fluid through the capillary wall. In 1948 Pappenheimer & Soto-Rivera (282) found in the denervated, perfused extremities of cats and dogs that a given change of venous pressure influenced filtration and absorption five to ten times more than did a similar change of arterial pressure. They formulated the dependence of mean capillary pressure on arterial and venous pressures and resistances as follows:

$$P_C = \frac{\frac{r_v}{r_a} p_A + p_v}{1 + \frac{r_v}{r_a}} \quad (2.1)$$

in which r_v and r_a are, respectively, the precapillary and postcapillary resistances, while p_A and p_v are, respectively, arterial and venous pressures. From this equation it follows that at given values of arterial

and venous pressures the mean capillary pressure depends on the ratio of the postcapillary to precapillary resistance to blood flow. Contractility of the large veins has been well established for a long time, but even in 1950 a general review (210) revealed little information concerning reactions of small veins or venules and only a few instances of independence of such reactions from those of the arterioles.

Beginning in 1954 Haddy *et al.* (137) approached the question of differential changes in precapillary and postcapillary resistances by threading catheters, outside diameter 0.2 to 0.5 mm, as far as possible into "small veins" and "small arteries" for measurement of pressures. Under control conditions small artery pressures averaged 65 ± 25 mm Hg, while small vein pressures, under local anesthesia, averaged 13 mm Hg with a range of 8 to 25 mm. Small vein pressure varied independently of the relatively constant large vein pressure, indicating that the small vein system must be responding independently to nervous or humoral stimuli. Kelly & Visscher (171) found that independent pressure changes in small arteries and small veins were produced by stimulating the lumbar sympathetic chain in dogs. Variability of these changes in timing, magnitude, and even direction was considerable and three main types or combinations of pressure changes had to be described. In further studies small vein pressure increased to as much as 36 mm Hg and led to the suggestion by Lee & Visscher (214) that edema of the skin could have a neural origin. However, were this an important possibility one would expect that cutaneous edema would be observed at some stage in the progressive, neural vasoconstriction found in hemorrhage and shock. This is, however, not the case. It must be remembered, too, that if arterial pressure remains constant, or especially if it falls, any constriction, whether arteriolar or venous, tends to reduce blood flow and this then tends to limit edema formation to the extent that renewed volumes of blood plasma are not available for filtration; at zero blood flow even the wheal of histamine does not appear (216, 217, 219).

Extending this method to humoral agents, Haddy and others found that independent, and sometimes opposite, reactions of arteries, small arteries, small veins, and large veins were produced by change of tissue temperature (135, 364), change of pH (105), epinephrine (134), norepinephrine (134, 364), serotonin (134, 136) and histamine (133). As summarized by Haddy *et al.* (134), "almost every possible combination of active and passive change in seg-

FIG. 2.5. Effect of histamine infused intra-arterially upon vascular and interstitial pressures in the dog's foreleg. Numbers at top refer to $\mu\text{g}/\text{min}$ histamine base administered into the brachial artery. [From Haddy (133).]

mental resistances and pressures has been observed during one or another arrangement." The true significance of these findings is correspondingly difficult to evaluate. In the case of histamine (fig. 2.5), which has been more thoroughly studied at controlled flow rates, this elevation was ascribed for small doses simply to arteriolar dilatation, and for large doses to an added selective constriction of small veins. This constriction in turn was ascribed in part to the direct action of histamine and in part to indirect effects stemming from release of norepinephrine from the adrenal medulla. It was suggested also that the resulting changes of capillary pressure might be sufficient to explain the protein-rich edema, produced by histamine, on hydrostatic grounds by passive congestion, increased capillary pressure and stretching of the capillary wall, without invoking injury of the wall by histamine. The production of a protein-poor filtrate is certainly possible, but the production of a protein-rich filtrate seems unlikely. The small vein pressures reported were all below 40 mm Hg, whereas it has been shown, with venous pressures of 40 to 60 mm Hg, that capillary filtrate contained at most 0.7 g per cent of protein and averaged only 0.3 g per cent (211), not the 4 or 5 g per cent found in the histamine wheal (217).

The validity of conclusions based on such catheterization of small veins is doubtful for several reasons. In addition to inescapable, even though slight, obstruction to venous outflow and false elevations of "small vein pressure" there is the possibility of effects from trauma to the intima of the venules under study. Davis & Hamilton (65-67) stimulated the

sympathetic nerves to the rabbit's ear and the dog's paw and found that the pressures developed in the small veins depended upon the nerve stimulated, upon the frequency of stimulation, upon the rate of blood flow, and upon the presence or absence of mechanical obstruction to venous outflow. They found also that the highest small vein pressures occurred while flow in the region had stopped. Pressures in the small veins sometimes exceeded those in the small arteries (fig. 2.6, right). They concluded that when this occurred the walls of the small veins were constricting against a static column of blood isolated probably from the capillaries, and certainly from the arterioles. Burch (29) observed similar elevations of pressure in isolated segments of large veins in man.

More recently still, an isovolumetric technique has been used by Mellander (243) to measure the effects of sympathetic stimulation on the resistance and capacitance vessels in cats with hind legs placed in a plethysmograph. As shown in figure 2.7, frequency of stimulation was kept within physiological limits, i.e., from 0.25 to 16 stimuli per sec. Both the capacitance vessels and resistance vessels constricted. The former responded more actively at first and reached maximum constriction at 8 stimuli per sec. The resistance vessels were influenced less at low stimulation rates and more at higher rates. Precapillary resistance increased more than postcapillary resistance and increasing absorption was found, with calculated reductions of capillary blood pressure ranging from 2 to 15 mm Hg. Mellander suggested that Kelly and Visscher, by manipulating and cannulating the small veins, may have produced local constriction of their walls. In addition to the obstruction already mentioned, it is also possible that intimal irritation, secondary to catheterization or cannulation, may make the small veins abnormally susceptible to vasoconstrictor impulses. In any event it seems clear that, under some conditions, stimulation of sympathetic vasoconstrictor nerves increases arteriolar resistance more than venous resistance, reduces capillary blood pressure, and leads to rapid and significant absorption of fluid and not to elevated capillary pressure and filtration.

By the same technique Mellander showed that epinephrine in small doses, and in muscle, relaxed the arterioles and probably constricted the venules slightly, producing filtration and hence indirect evidence of a rise of capillary blood pressure. In skin, all doses, and in muscle large doses of epinephrine produced effects like those of sympathetic stimulation, but only 20 to 25 per cent as great. Norepi-

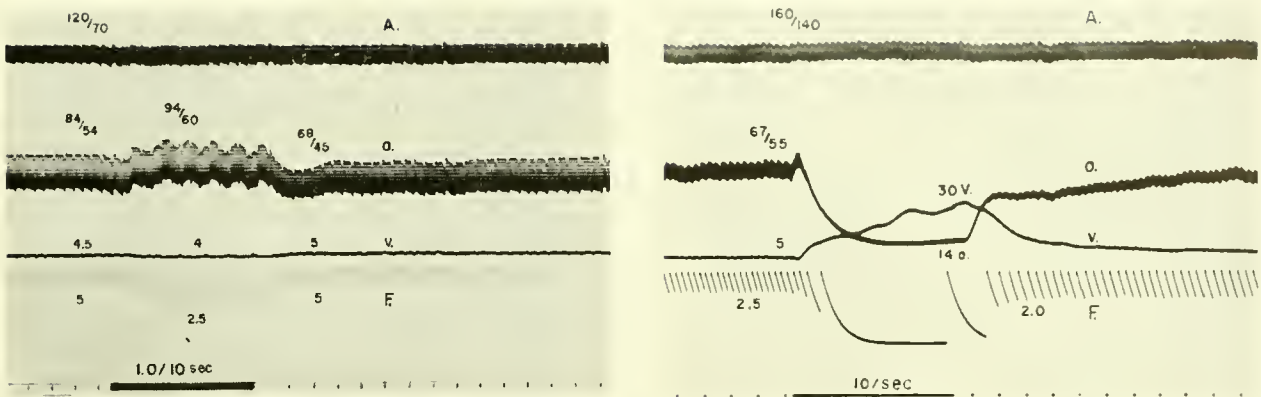

FIG. 2.6. *Left:* small vessel pressure and flow response to a low-frequency stimulation of the ipsilateral lumbar sympathetic trunk (15 v, 1 stimulation/10 sec for 1 min) Aortic pressure (A), small artery pressure (a), small vein pressure (v), and small vein flow (F) against atmospheric pressure. Numerals on pressure tracings indicate pressure in mm Hg. Numerals on flow tracing represent flow in ml/min. Timer set at 10 sec. *Right:* same but with high frequency stimulation (15 v, 10 stimulations/sec for 1 min). Symbols same except that F is small artery flow proximal to distal segment. [From Davis & Hamilton (66).]

FIG. 2.7. Effects on resistance and capacitance vessels and net transcapillary fluid shift produced by maximal lumbar vasoconstrictor fiber stimulation at different frequencies. Changes in blood flow reflect effects on resistance vessels (inflow and outflow pressures kept constant). The initial and rapid decreases in volume reflect effects on capacitance vessels and the subsequent slower and continuous decreases in volume (slopes indicated by dashed lines), transcapillary influx of extravascular fluid. Reductions in mean hydrostatic capillary pressure calculated in approximate figures. [From Mellander (243).]

nephrene was also constrictor and produced absorption of fluid. Acetylcholine increased blood flow markedly but produced less filtration than small doses of epinephrine. Presumably capillary pressure increased very little because pre- and postcapillary resistances were reduced equally. Johnson and Hanson (168a) have recently applied the isogravimetric technique

to a study of pre- and postcapillary resistance in the intestine of the dog. In this preparation, the isogravimetric capillary pressure is only about 65 per cent of the plasma protein osmotic pressure, probably reflecting the higher permeability to protein of intestinal capillaries. The postcapillary resistance to blood flow through the intestine was increased markedly when

arterial perfusion pressure was decreased and evidence was presented that this reaction depends upon sympathetic innervation of the postcapillary blood vessels (142a).

One more series of studies must be mentioned briefly because the possible role of the arteriovenous anastomoses on small vein pressures has not been mentioned so far. These relatively large vessels run parallel to the capillaries and are numerous in the skin, particularly of the digits. Schroeder (324), using a pressure plethysmograph similar to that used in man by McLennan *et al.* (234), studied the effects of acetylcholine, epinephrine, histamine (325), hypoxia (327), calcium, and rutin (326) on vascular volumes and pressures in the dog's foreleg. External pressure was set arbitrarily at 35 mm Hg to measure "changes of capillary pressure" and at 15 mm Hg to measure "changes of venous pressure." No absolute pressure readings could be obtained by this method. The curves were variable and often difficult to interpret. However, Schroeder placed considerable emphasis upon independent reactions of the arteriovenous anastomoses and their secondary effects upon venous and capillary pressures. It is conceivable that some of the variability in the observed small vein pressures in the skin of the extremities may be reduced, or at least explained in part, if body temperature and environmental temperatures are adjusted to maintain the arteriovenous anastomoses in as constant a state as possible. In any case it is clear that pressures and resistances in large veins and in small veins, together with any factors which modify them, must be taken into account when describing the mechanisms which determine changes of capillary blood pressure.

3. OSMOTIC PRESSURE OF THE PLASMA PROTEINS, Π_{pl}

A. Methods of Measurement

Starling's conception of a balance between capillary hydrostatic pressure and protein osmotic pressure was supported by actual measurement of the pressure required to maintain fluid balance across a semi-permeable membrane separating blood serum from serum ultrafiltrate. Starling's osmometer consisted of a small glass bell, provided at the top with two side arms. A piece of peritoneal membrane, soaked in 10 per cent gelatin, was tied over the mouth of the bell and prevented from bulging by a perforated silver plate. One sidearm was connected to a vertical tube and the other side arm was used to introduce serum into the bell. The lower end of the bell, in-

cluding the membrane, was then dipped into serum ultrafiltrate or other protein-free salt solution. Within a few hours osmotic flow of fluid from the salt solution through the membrane was made evident by a rise of fluid in the vertical tube. Equilibrium was established in 2 to 6 days; at this time the pressure on the membrane, exerted by the fluid column in the vertical tube, was considered equal and opposite to the osmotic pressure of the serum proteins. In a typical measurement Starling (345) found that serum containing 7.56 per cent "proteids" caused fluid to rise in the vertical tube to a height of 53 cm (~ 41 mm Hg). This value is considerably higher than modern estimates shown in figure 3.1, probably as a result of bacterial degradation of protein during the long period required to reach equilibrium. In later work (1899) Starling (347) obtained values which were generally lower than his first estimate and well within the range expected for capillary hydrostatic pressures.

Starling's measurements were of great interest to colloid chemists as well as to physiologists. According to van't Hoff's analogy, in 1887, between ideal solutions and gases (157), the osmotic pressure, Π , should be given by

$$\Pi = cRT \quad (3.1)$$

where c is expressed in moles per liter.

FIG. 3.1. Osmotic pressure-concentration curves for whole plasma and selected plasma proteins. Based on data from references (268, 270, 312, 313, 343), original measurements corrected to 37°C. Experimental points for γ -globulin are included to indicate magnitude of experimental error.

FIG. 3.2. First derivative of protein osmotic pressure-concentration curve to show deviation from van't Hoff's law. At infinite dilution the mean number average molecular weight of plasma proteins is almost 100,000 but in normal plasma their osmotic behavior corresponds to an ideal solute of mol wt 37,000.

If c is expressed in g per 100 ml, RT in liter-atmospheres, and Π in atmospheres, then

$$\text{Mol. Wght.} = 10c \ RT / \Pi \quad (3.2)$$

The potential application of equation 3.2 to the determination of molecular weights led protein chemists to investigate in detail the theory and technique of osmotic measurements. As early as 1905, Reid (293) used Starling's technique to estimate the molecular weight of hemoglobin. Subsequent studies by Sørensen (342), Adair (1, 2), and others showed that protein osmotic pressure is dependent upon ionic strength, net charge, and other factors not included in van't Hoff's limiting law for ideal solutions. Deviations from the limiting law increase rapidly as a function of protein concentration (figs. 3.1 and 3.2) and estimates of molecular weight can only be made on the basis of extrapolation to zero concentration. The chief technical difficulty confronting early workers was the long period required to reach equilibrium across artificial membranes. In order to avoid bacterial degradation of protein it was necessary to carry out measurements at low temperature; days or even weeks were required for each determination. Nevertheless, the first satisfactory estimates of the molecular weights of serum albumin (3), ovalbumin (342), and hemoglobin (2) were obtained by this method.

Advances in the technique of osmometry have reduced considerably the time required for the equilibration process.

Equilibration across a semipermeable membrane, following a step change in either hydrostatic or osmotic pressure, proceeds exponentially with a time constant equal to the product of membrane resistance and volume distensibility

$$\% \text{Equilibrium} = 100 \left[1 - \exp \frac{-t}{r_m(v_p + v_m)} \right] \quad (3.3)$$

where r_m is membrane resistance to solvent flow and v_p , v_m are the volume distensibilities of the pressure measuring device and membrane, respectively. The resistance (r_m) of membranes capable of restraining the passage of serum albumin is seldom less than 10^4 mm Hg per ml per hour per cm^2 membrane. The essential factor limiting the rate of approach to equilibrium is therefore the volume of fluid which must pass through the membrane in order to actuate the pressure detector and satisfy the volume-pressure characteristics of the membrane. For example, a typical osmometer with a membrane surface area of 10 cm^2 must have a total volume distensibility of less than 3×10^{-4} ml per mm Hg in order to achieve 95 per cent equilibrium in 1 hour (equation 3.3).

In 1936 Hepp (151) described an osmometer in which distensibility of the membrane (v_m) was made extremely small, the chief volume displacement being confined to slight changes in fluid level of the capillary tube manometer used to detect pressure balance. Equilibration time was reduced to about 2 hours. Osmometers of the Hepp type have been widely used by subsequent investigators and the osmotic pressure-concentration curves shown in figure 3.1 are based on data obtained with this instrument. A recent description of the construction and use of Hepp osmometers has been published by Meschia (248). Further reduction in volume displacement can be obtained through the use of sensitive, recording pressure transducers having volume distensibilities less than 10^{-6} ml per mm Hg. With the aid of such transducers it is theoretically possible to achieve 95 per cent equilibration across available protein-impermeable membranes in less than 1 min. Recording osmometers of this type, having time constants of less than 5 min, have been in use in the authors' laboratory for several years (277, 280). Similar instruments, suitable for the rapid estimation of protein osmotic pressure in 0.1 ml plasma, have recently been described by Hansen (142).

B. Protein Osmotic Pressure of Human Plasma

Osmotic pressure-concentration curves for normal human plasma, serum albumin, and two globulin components of plasma are shown in figure 3.1. The curves were obtained at physiological pH and ionic strength, but the original measurements have been corrected to 37 C. Experimental points, taken from Oncley *et al.* (268), are shown for γ -globulin in order to indicate the magnitude of experimental error when a pure component is measured. The smooth curves for albumin, whole plasma, and β_1 -globulin are based on data in references (268, 270, 312, 313, 343). Normal human plasma has a

protein osmotic pressure of 24 to 26 mm Hg, corresponding to a total protein concentration of about 7 per cent. It is impossible to give a significant mean value because the protein concentration depends upon procedures used for drawing blood samples and in any given sample the value obtained depends upon the method of measurement. Electrophoretic measurements yield slightly lower values for total protein than estimates based upon salt precipitation or protein nitrogen. In the following discussion a nominal value of 7.0 g per 100 ml will be considered normal.

The osmotic pressure-concentration curves for albumin and for normal plasma are described by the following empirical equations which fit the experimental data closely over the range 0 to 25 per cent protein.

$$\pi \text{ albumin} = 2.8c + 0.18c^2 + 0.012c^3 \quad (3.4)$$

$$\pi \text{ plasma} = 2.1c + 0.16c^2 + 0.009c^3 \quad (3.5)$$

In each equation the first term represents the ideal limiting law of van't Hoff. Thus the molecular weight of albumin, calculated from the first term of equation 3.4, is $10 RT/2.8 = 69,000$. The second and third terms in each equation represent deviations from van't Hoff's law caused by Donnan effects and protein-protein interaction.

The chief osmotically active protein in normal mammalian plasma is albumin, which can be separated and identified as a homogeneous component representing about 50 per cent of the total protein in plasma and contributing about 65 per cent of the protein pressure. The globulins, on the other hand, comprise a spectrum of components with molecular weights ranging from 45,000 to 1,000,000 as shown in table 3.1. The widely different osmotic activities of β_1 -globulin and γ -globulin shown in figure 3.1 serve to emphasize that no simple physicochemical meaning can be attached to the osmotic pressures developed by crude, heterogeneous globulin fractions. Precipitation methods fail to separate albumin from low molecular weight globulins which contribute substantially to total protein osmotic pressure; for this reason many early studies attempting to relate total protein pressure to albumin:globulin ratios (380) need to be reevaluated. Current estimates of A:G ratio in normal plasma are close to 1.1, in comparison with values in the range 1.8 to 2.6 obtained by classical fractionation procedures.

The osmotic pressure contributed by globulins can be calculated from the difference between albumin and whole plasma (equations 3.4, and 3.5),

it being assumed that the A:G ratio is 1.1 and that osmotic interactions between globulins and albumin are not significantly different from interaction between albumin and albumin (270, 314). The "average" globulin curve so calculated is given by

$$\pi \text{ globulins} = 1.6c + 0.15c^2 + 0.006c^3 \quad (3.6)$$

In normal plasma about 15 per cent of the total protein pressure is contributed by known globulin components and about 20 per cent by unidentified components (table 3.1). Bennhold *et al.* (14) have studied two extremely interesting cases of complete analbuminemia; the osmotic pressure-concentration curve of the albumin-free plasma from these unique patients (brother and sister) conforms closely to equation 3.6 (271). These patients have been in good health for many years despite the fact that the protein osmotic pressure of their plasma is less than 50 per cent of normal. Presumably they have compensated by permanent reduction of mean capillary pressure to balance the low protein pressure.

C. Species Differences, Fetal Plasma

Comparative studies of colloid osmotic pressure have been reviewed by Meyer (251) and by Keys & Hill (175). A summary of data pertaining to plasma of Elasmobranchs, Pisces, Amphibia, Reptilia,

TABLE 3.1. *Some Protein Components of Human Plasma**

| Component | Conc. g/100 ml | % of Total Protein | mol wt | Approx. π in Plasma mm Hg |
|------------------------------------------------|----------------------|--------------------------|-----------------|-------------------------------------|
| Whole plasma | 7.0 | 100 | | 25 |
| Albumin | 3.6 | 51 | 69,000 | 16.4 |
| γ -Globulins | .7 | 11 | 156,000 | 0.9 |
| Fibrinogen | .3 | 4 | 340,000 | 0.2 |
| α -Lipoprotein ($1.0 < p < 1.14$) | .28 | 4 | 160-400,000 | 0.2 |
| β -Lipoprotein ($p = 1.03 \pm .02$) | .25 | 3.8 | 2×10^6 | |
| β_1 -Metal combining | .2 | 3 | 90,000 | 0.7 |
| β_2 -Globulins | .2 | 3 | (150,000) | 0.4? |
| β_1 -Lipid poor euglobulin | .13 | 2 | (150,000) | 0.2? |
| α_1 -Acid glycoprotein | .03 | 0.4 | 45,000 | 0.2? |

| Total | 6.0 | 87 | | ca. 20 |
| Unidentified | 1 | 13 | | 5 |

* Prepared with J. L. Oncley; cf also ref. 267.

Aves, and Mammalia will be found in reference (4). It is a striking fact that all mammals have approximately the same protein osmotic pressure. Mean values for the various species of mammals listed by Meyer (251) range from 19 mm Hg (guinea pig) to 26 mm Hg (human), but data from most species lie in the range 21 to 25 mm Hg. These relatively small variations among species may well be spurious. Excitement, posture, anesthesia, and many other factors can cause substantial hemodilution or hemoconcentration prior to withdrawal of blood samples. It would be unjustified to compare blood obtained from a confident, unanesthetized human with blood obtained from animals in various states of excitement and anesthesia.

Protein concentrations and osmotic pressures in plasma of poikilotherms are in general far lower than in mammals. Values in the range of 5 to 10 mm Hg have been reported for frogs and turtles (35, 189, 200), the lower values being associated with the spring season. The low protein osmotic pressure of poikilotherms is to be expected in view of their relatively low blood pressure. It is surprising, however, to find similarly low values in birds in which blood pressure is relatively high.

The protein osmotic pressure of fetal plasma is of special interest in relation to fluid exchanges between maternal and fetal blood. Meschia (249) has carried out a careful series of osmotic measurements in fetuses from sheep and goats. At midterm the protein osmotic pressure in fetal blood is 7 to 10 mm Hg; the pressure gradually increases during gestation but never exceeds that in maternal blood. The average molecular weight of proteins in fetal plasma is only 65,000 as compared with 96,000 in the adult. This difference is largely due to the presence of fetuin (283a), a low molecular weight globulin which accounts for about 90 per cent of the globulin fraction. The mean molecular weight increases dramatically within 24 hours after birth, owing partly to absorption and retention in the blood of γ -globulins from colostrum.

D. Physiological Significance of the Deviations from van't Hoff's Law

The disproportionate increase in protein osmotic pressure as a function of concentration tends to amplify osmotic forces contributing to homeostasis of blood volume. The magnitude of this effect is seldom appreciated and will therefore be discussed in some detail. Figure 3.2 shows the rate of change of

osmotic pressure per unit change in concentration, as a function of concentration. At small protein concentrations, such as those existing in tissue fluids, the osmotic coefficient, $d\Pi/dc$, is relatively small and the proteins behave as the osmotic equivalent of an ideal solute of molecular weight 80,000 to 90,000. Thus the osmotic forces in interstitial fluid tending to withdraw fluid from blood are relatively small and insensitive to quite large percentual alterations in protein concentration. At concentrations which exist in plasma, however, the osmotic coefficient is almost threefold greater so that the plasma proteins behave as the osmotic equivalent of an ideal solute of molecular weight 37,000. If the proteins behaved as ideal solutes they would have to be present in plasma at a concentration of 12 per cent in order to exert the same osmotic pressure. The viscosity of such a concentrated solution would more than double peripheral resistance to blood flow. On the other hand, an ideal solute of molecular weight 37,000 (i.e., osmotically equivalent to the proteins in plasma) would pass rapidly through the capillary walls and therefore be ineffective in balancing capillary hydrostatic pressure.

The functional significance of the nonlinear osmotic properties of the plasma proteins is further illustrated in figure 3.3. Fluid loss from plasma, amounting to

FIG. 3.3. Physiological significance of deviations from van't Hoff's law. Fluid loss from plasma causes a disproportionately large increment in the osmotic restoring force; conversely, hemodilution causes a relatively small diminution of protein osmotic pressure.

FIG. 3.4. Illustrating the significance of protein osmotic pressure for glomerular filtration. The rapid increase of protein osmotic pressure as a function of concentration places an upper limit to the filtration fraction of the kidney.

30 ml per 100 ml, results in an increase of 18 mm Hg in the osmotic restoring force, resisting further fluid loss. If the plasma proteins behaved as ideal solutes, however, the restoring force would be only 6 mm Hg. Conversely, dilution of the plasma results in a greater reduction of osmotic pressure than would obtain if the proteins behaved as ideal solutes. These considerations are of special importance normally in connection with glomerular filtration where a relatively large fraction of plasma fluid may be filtered. Figure 3.4 shows protein osmotic pressures in efferent glomerular blood as a function of filtration fraction. It is clear that the steep rise of protein osmotic pressure is an important factor limiting filtration rate. For example, a filtration fraction of 0.45 is the highest possible value consistent with a normal plasma protein concentration (ca. 7%) and a normal hydrostatic pressure (ca. 70 mm Hg) in the glomerular capillaries. It is probable also that the high protein osmotic pressure in efferent glomerular blood plays a major role in providing the force for transcapillary absorption of fluid in the peritubular circulation.

E. Physicochemical Aspects of Protein Osmotic Pressure

In the preceding paragraphs we have emphasized the functional significance of the large deviations from van't Hoff's law which characterize osmotic behavior of plasma proteins. It therefore seems appropriate to discuss briefly the physical forces which contribute to nonlinear osmotic behavior of this type.

The disproportionate increase in osmotic pressure as a function of protein concentration (figs. 3.1 and

3.2) can be explained in part by net charges on the protein molecules which cause unequal distribution of electrolytes across the semipermeable membrane (Donnan effect). Combination of van't Hoff's limiting law (equation 3.1) with the ionic distribution required by Donnan equilibrium for univalent ions yields the following relation.

$$\Pi = RT(c + \sqrt{z^2 c^2 + 4m_s^2} - 2m_s) \quad (3.7)$$

where c = protein concentration, moles per liter; z = net charge² on the protein, and m_s = the concentration of salt solution with which the protein is equilibrated. A simple derivation of equation 3.7 may be found in reference (156). A more convenient form of equation 3.7 may be obtained from expansion of the second term by means of the binomial theorem. Thus,

$$\sqrt{z^2 c^2 + 4m_s^2} = 2m_s + \frac{z^2 c^2}{4m_s} - \frac{z^4 c^4}{64m_s^3} + \dots \quad (3.8)$$

The third term of the series is negligible except at very low salt concentrations. Substituting the first two terms of the series in equation 3.7 we obtain the form derived by Scatchard *et al.* (313)

$$\Pi = RT\left(c + \frac{z^2 c^2}{4m_s}\right) \quad (3.9)$$

Equation 3.7 or 3.9 describes qualitatively some of the observed changes in osmotic pressure as a function of protein concentration, charge, and salt concentration. Thus osmotic pressure is increased when the salt concentration (m_s) is reduced or if the charge (z) is increased in either direction from the true isoelectric point. For a limited range of conditions, equation 3.7 or 3.9 predicts quantitatively the observed osmotic pressure-concentration curves.

For example, when albumin is equilibrated against .15 M NaCl ($m_s = .15$) at pH 7.4 the charge, z , is -17 , whence

$$\Pi = RT\left(c + \frac{17^2}{4 \times .15} c^2\right) \quad (3.10)$$

Taking 69,000 as the molecular weight of albumin and expressing c in g per 100 ml this becomes

$$\Pi = 2.8c + 0.19c^2 \quad (3.11)$$

Equation 3.11 is almost identical with the first two

² Net charge, z , is defined as the algebraic sum of all charges on the ionizable constituents of the protein molecule plus those charges which result from binding of ions by the protein. In the case of serum albumin at pH 7.4 in .15 M NaCl at 25°C the net charge estimated from the titration curve is -17 , made up of approximately 100 negative and 83 positive charges on the protein. In addition 9 or 10 chloride ions are bound to each molecule (86).

terms of the empirical equation 3.4 describing the observed osmotic pressure-concentration curve for albumin under the stated conditions (fig. 3.1). This close correspondence between observed osmotic pressure and the pressure calculated on the basis of Donnan theory might lead one to believe that the problem has been solved. Unfortunately, this is not the case. The correspondence between theory and fact only occurs at two particular values of charge, one of which occurs (fortuitously) at physiological pH and salt concentration. Figure 3.5 shows clearly the discrepancy between observed osmotic pressure and the theoretical pressure predicted on the basis of Donnan theory and van't Hoff's law. This discrepancy may be explained in part by the binding of chloride ions to the albumin molecule (86, 315). Binding of chloride (or other anions) to the protein decreases the fraction of salt free to take part in the Donnan distribution and at the same time causes an error in the calculation of net charge from titration data. For this reason, also, the isoelectric point differs from the isoionic point (86). When corrections are made for chloride binding it appears that the true isoelectric point for albumin is closer to pH 4.2 than to pH 5.4 as might be inferred from its titration curve. As shown in figure 3.5, the osmotic pressure does approach the van't Hoff pressure at pH 4.2 as would be

predicted from the Donnan relation (equation 3.6) for the case $z = 0$.

Even after corrections have been made for chloride binding, however, the Donnan theory fails to account quantitatively for observed osmotic pressure under most circumstances. Other factors involved include electrostatic interactions between protein molecules and between protein and salt. These interactions are presumably represented in the third term of the empirical equations (e.g., equation 3.4) describing osmotic pressure-concentration curves, but no precise theoretical explanation of these forces can be offered at the present time.

4. INTERSTITIAL FLUID PRESSURE ("TISSUE PRESSURE"), P_{if}

Capillary blood pressure is only one point on the transmural gradient of hydrostatic pressure which is concerned with the filtration of fluid through the capillary wall. The other point is the pressure on the interstitial fluid outside the capillary wall. Landerer (197) in 1884 attempted the first direct measurements of interstitial fluid pressure by introducing a fine cannula or needle into the subcutaneous or cutaneous tissues and recording the pressures required to cause fluid to flow into the tissues. Landerer's figures, like those of Hajen (139) and others (158, 252) proved to be fallacious because too much fluid was injected before pressure was measured (238). Nevertheless these experiments were significant because they showed that considerable resistance must be overcome if the volume of interstitial fluid is increased suddenly.

Even when the volume of interstitial fluid was increased more gradually and physiologically, evidence of mounting interstitial fluid pressure appeared almost at once, at least in some tissues. Drury & Jones (80) used an ordinary plethysmograph to measure rates of filtration in the leg during venous congestion, and found this rate declined as filtration progressed, though their figures were irregular because their method measured changes of vascular volume and of interstitial fluid volume together. A "pressure plethysmograph" (188, 209) made it possible to exclude changes of vascular volume and thereby to measure changes of interstitial fluid volume more accurately. Landis & Gibbon (209) found in the human forearm that the filtration produced by given venous pressures declined rapidly, beginning even during the first 10 min of filtration. With a venous pressure of 20 cm of water, filtration ceased in 35 to 55 min after the accumulation of less than 1 ml of filtrate per 100 ml

FIG. 3.5. Illustrating the discrepancy between osmotic pressure calculated on the basis of Donnan theory and protein osmotic pressure measured experimentally. Agreement with theory occurs fortuitously at pH 4.7 and pH 7.6. [Calculated from data in reference (313).]

FIG. 4.1. Chart showing decreasing filtration rate (----- in *A*) measured in human forearm by pressure plethysmograph when venous pressure was elevated to 60 cm H₂O for 80 min. Interstitial fluid pressure (O—O) was calculated by dividing the cumulative decrease of observed filtration rates by the previously determined average normal filtration coefficient (.0033 ml/100 ml forearm tissue/min/cm H₂O increase of venous pressure), and then correcting each value for the local increase of plasma protein concentration and of Π_{pl} produced by net filtration. As shown in *A* calculated interstitial fluid pressure increases steadily with time, reaching a maximum of almost 30 cm H₂O by 75 min. In *B* the same calculated interstitial fluid pressures are charted against the cumulative volume of added interstitial fluid. As the interstitial compartment is distended by an increasing volume of filtered fluid, interstitial pressure in the forearm tissues probably rises slowly at first and then more rapidly. [Recalculated from data of Landis & Gibbon (209).]

of forearm tissue. As shown in figure 4.1 (*left*) when venous pressure was raised to 60 cm water, the initial filtration rate was .156 ml per min per 100 ml of forearm tissue but declined rapidly to less than .040 after 75 min of congestion. At this time the volume of newly filtered fluid was approximately 6 ml per 100 ml of tissue, i.e., about 60 per cent of the amount which produces manifest edema, detectable by "pitting on pressure." Knowing the decrease of filtration rate, the normal filtration coefficient (209), and, approximately, the increase in the osmotic pressure of the plasma proteins of the blood in the congested forearm (188, 211), it is possible to calculate interstitial fluid pressure, with results shown in figure 4.1.

Accumulations of interstitial fluid from prior filtration also increased the rate at which extravascular fluid was removed from the forearm (188, 209), as would be expected with higher interstitial fluid pressures. It is still impossible to decide to what extent this fluid was removed via the blood capillaries by absorption or via lymphatics by flow, though indirect evidence (188) indicated that small accumulations were probably removed by the former, larger accumulations by the latter in addition. The importance of

interstitial fluid pressure seemed clear, although dependable direct measurements were not available as yet.

In a review of this topic in 1934 (207) it was necessary to consider the conflicting views then current concerning bound and free water in the interstitial fluid compartment. It is now generally agreed on the basis of many studies by several dilution methods that the volume of truly "bound water" is negligible. Yet in normal tissues interstitial fluid cannot be identified microscopically as a distinct and continuous compartment or layer around capillaries or between cells except in a few locations. This is not surprising because a simple calculation shows that if the normal volume of interstitial fluid, approximately 15 per cent of gross tissue volume, is distributed uniformly between surfaces of cells, connective tissue fibrils, blood capillaries, etc., the average thickness of this layer cannot be greater than 1 μ and is probably less than 0.5 μ . This coincides with the findings of McMaster & Parsons (240, 241) who injected dye solutions into small lymphatic vessels and observed under high magnification that the dye penetrated into the tissues in the form of hair-like projections or "bristles,"

apparently between or along connective tissue fibrils (fig. 4.2). Hemorrhage and dehydration, which they used to diminish the volume of interstitial fluid, delayed the appearance of these bristles of dye, but eventually they became clearer than usual, as well as more resistant to displacement by massage. On the other hand, hydremic plethora, and particularly the edema of inflammation, tended to obliterate the bristles and permitted instead a diffuse and more rapid distribution of dye which could easily be displaced by pressure from one area into another, presumably because it dissolved in a larger and more freely movable volume of edema fluid.

The paucity of normal interstitial fluid, its layered distribution, and the disruptive effects of injecting even small volumes of fluid (238) makes it necessary, as with capillary blood pressure, to determine interstitial fluid pressure by a "null point" method which provides a balance of pressures with minimal movement of fluid into, or out of, the interstitial fluid compartment. Wells *et al.* (375) used a capillary tube placed between the manometer and the saline-filled needle that was inserted into the tissue. By observing the meniscus under a microscope, they saw that a

change of 2 or 3 mm water pressure sufficed to reverse the flow at the point of balance and hence, after correcting for capillarity in the tube, they measured interstitial fluid pressure with a small volume artifact. Burch & Sodeman (30) and McMaster (238) reduced the volume change further, but still more refined methods are needed to reduce the likelihood of local hemorrhage and mechanical artifacts.

Table 4.1 summarizes several representative series of values given in mm Hg for easier comparison with capillary blood pressure and the osmotic pressure of the plasma proteins. In skin, McMaster (238) found it necessary to determine "interstitial resistance" to very slow rates of inflow of fluid because paucity of freely movable fluid prevented determining a true interstitial pressure. Although some of the values in table 4.1 may be artificially high, their order of magnitude is consistent. P_{if} in skin and subcutaneous tissues, under resting conditions, ranges from 1 to 5 or 6 mm Hg and averages about 2.5 mm Hg. In muscle, P_{if} tends to be slightly higher, 1 to 9 mm Hg and averages 4.5 mm Hg. In some comparisons P_{if} was higher in the tightly sheathed muscles, e.g., soleus and anterior tibial, than in the more loosely enclosed

FIG. 4.2. Diagrammatic sketch of the extravascular interstitial movement of a 2% solution of pontamine sky blue after its escape from the lymphatics. *a*: Dye first appears as colored bristles at 2-7 min. *b*: Color becomes more intense and bristles longer at 3-10 min. *c*: Colored lines become broader at 5-12 min. *d*: Second phase. Diffuse blue staining between bristles which cannot be dislodged by pressure. Bristles disappearing. During *a* to *d* color was apparently fixed on tissue elements and not dislodged by pressure. *e*: Diffuse blue cloud easily displaced with pressure, free fluid. *f*: Dye escaping from ruptured lymphatics, no bristles. [From McMaster & Parsons (240).]

TABLE 4 1. *Interstitial Fluid Pressure, P_{if} , Ranges at Rest*

| Tissue, Species | Pressure (Range) mm Hg | Reference |
|-------------------|---------------------------|-----------|
| Subcutaneous, man | | |
| Forearm and leg | 1.5-5.1 | (375) |
| Foot | 1.1-3.2 | (30) |
| Pretibial | 1.3-4.0 | (30) |
| Forearm | 0.8-2.9 | (30) |
| Hand | 0.6-2.2 | (30) |
| Foot | 1.2-3.0 | (231) |
| Leg | 4.1-6.5 | (231) |
| Eyelid | 1.2-3.0 | (28) |
| Cutaneous | | |
| Mouse* | 0.4-3.7 | (238) |
| Man* | 1.8-4.9 | (238) |
| Muscle, man | | |
| Gastrocnemius | 0.7-3.7 | (375) |
| Soleus | 3.7-7.3 | (375) |
| Gastrocnemius | 2.6-8.9 | (231) |
| Biceps | 3.2-6.6 | (231) |
| Biceps | 2.9-6.6 | (127-129) |

* "Interstitial resistance" to very slow flow, probably 0.5 mm above P_{if} (238).

gastrocnemius and biceps (375). Very high pressures, up to 85 mm Hg, were found briefly in some muscles during powerful contractions (375), and values lower than average were common during anesthesia, hemorrhage, surgical operations, and shock (127-129).

The effects of venous congestion, and consequent filtration, on directly measured P_{if} have been highly variable, depending, as might be expected, upon the

distensibility of the tissue studied. McMaster (239) found pressures up to 32 cm water or 23 mm Hg in the skin of the mouse (fig. 4.3), and up to 23 cm water or 17 mm Hg in human skin, in good agreement with the calculated interstitial fluid pressures found by Landis & Gibbon (209) in the congested forearm (fig. 4.1). Mayerson & Burch (231) found much lower maximum pressures in subcutaneous tissue of man during venous congestion or during quiet standing, e.g., 5.6 to 8.8 cm water, while intramuscular pressure rose to maxima of 22 cm water in nonfainting subjects and only 11 cm water in fainting subjects.

In isolated, perfused extremities Hyman (162) and Pappenheimer & Soto-Rivera (282) found little interference with prolonged filtration, and hence no evidence of increased interstitial fluid pressure, until manifest edema appeared. Hinshaw & Day (155), however, made direct measurements of P_{if} in perfused extremities and found increases from control values of 0.5 and 1.2 mm Hg to 8 and 15 mm Hg when 1+ edema was present and to 10.5 and 24 mm Hg when 2+ edema had appeared. This pressure was enough to produce measurable collapse of blood vessels. If this collapse involves the small veins it may well distort fluid movement through changes in resistance to flow, as well as through direct opposition to capillary blood pressure itself.

Interstitial fluid pressures up to 25 mm Hg help explain the slowness with which edema forms in normal human beings, despite the high capillary pres-

FIG. 4.3. Changes of interstitial fluid pressure in the skin and lower leg of mouse during and after venous congestion of 40 mm Hg. Black dots indicate pressure readings which yielded neither inflow into the skin nor backflow into the apparatus; i.e., the pressure of the extravascular fluid was accurately balanced. Plus signs indicate pressure readings at which fluid moved into the tissues; i.e., pressure in the apparatus was above interstitial pressure. Minus signs show that backflow occurred into the apparatus and that the plotted pressure was lower than that of the extravascular fluid. The interstitial resistance during the control period is shown by asterisks. [From McMaster (239).]

tures and rapid initial filtration found in the lower extremities during sitting or quiet standing. However, the occurrence of edema indicates, of itself, that the tissue elements are slowly separable, and so cannot resist higher than normal interstitial fluid pressures indefinitely. P_{if} in manifest edema of man has proved to be highly variable though frequently above normal limits. During accumulation of edema fluid it ranged from 4 to 18 cm water in one series (336) and from 4 to 26 cm water in others (30, 340), returning in all instances toward normal or below as the edema fluid disappeared. Holland & Meyer (158) reported pressures below normal in edema, but their method was open to question (238). In the skin of the mouse McMaster (238) found that P_{if} was little elevated in some forms of experimental edema and greatly elevated in others with the further anomaly that in some instances beefy indurations occurred in which paucity of freely movable fluid permitted only measurement of interstitial resistance to slow introduction of fluid. In general, both clinically and experimentally, the highest interstitial fluid pressures were found in skin which had become recently and rapidly edematous. Slowly developing edema often occurred without significant elevations of P_{if} . The distensibility of tissues is also an important variable. The eyelids accommodated rapidly injected fluid most easily, the face and pretibial areas least easily (28). In edema P_{if} was found to be lower, 1 to 8 cm water in the former and higher, 2 to 14 cm water, in the latter.

The limited and transitory resistance of tissues to slowly introduced fluid has been described quantitatively by McMaster (237). At pressures ranging from 4.5 to 14 cm water the entry of Locke-Ringer's solution through a needle into a tissue was slow and also intermittent. Above these pressures, which he termed the "breaking point," fluid flowed into the tissue continuously and at much higher rates, which increased linearly with further pressure increments. Once the tissues had been separated by this "breaking pressure," high rates of flow were observed even at low pressures (237). The resistance which the normal interstitium offers to flow of filtered fluid from capillaries to lymphatics has been demonstrated in different fashion recently during venous congestion in the dog's leg by Irisawa & Rushmer (166). When venous pressure was elevated to between 65 and 55 cm water for 270 min the pressure in the draining lymphatic vessels rose very slowly reaching, after 90 min, plateaus of 18 cm water or less.

The positive interstitial fluid pressures so far described were obtained in acute experiments of rela-

tively brief duration. There is some evidence, however, that interstitial fluid pressure may be slightly but definitely negative under some conditions and in more prolonged observations. McMaster (235, 236) observed at atmospheric pressures that fluid flowed intermittently from a needle into cutaneous tissue at rates up to .08 mm³ per min. This suggests a negative interstitial pressure, but the subatmospheric pressure required to arrest inflow was not determined. Inflow of fluid was increased in transitory fashion by painful stimuli and by the intravenous injection of hypertonic sucrose solution. These changes are explicable on the basis of increased absorption by capillaries during vasoconstriction and decreased capillary blood pressure in the first instance, and by temporary hypertonicity of capillary blood in the second instance. Outflow of fluid, that could be arrested by positive pressure on the fluid in the needle, was found during venous congestion and when an irritant solution produced localized edema. These outflows may be explained respectively by heightened capillary pressure and by injury. On the other hand, the hyperemia induced by heat, either directly or reflexly, increased inflow of fluid into the tissue, despite observed vasodilatation and presumable elevation of capillary pressure. It is possible that locally increased arterial pulsation may, by pumping action, have evacuated the regional lymphatics and so increased inflow mechanically (283, 373).

Very recently Guyton *et al.* (130) have extended the time of observation to hours or days. Immediately after insertion of needles, and in agreement with previous studies, slightly positive readings, e.g., +1 to +2 cm water, were obtained. During the next 4 or 5 hours, however, the balancing, null-point pressures decreased gradually to -2 or -3 cm water with indications that this decline was still continuing. To extend readings to days or weeks, perforated plastic capsules were implanted in the subcutaneous tissue and after 1 or 2 weeks pressures were -3 to -14 cm water in the abdominal wall, axillary space, scrotum, muscle, and quiet limb. They decreased slowly, over a period of minutes, when the respective parts of the body were moved. Venous congestion changed the pressure to positive values, but not until edema was apparent. Protein in the capsule also produced positive values.

Chronic experiments of this type tend to avoid some of the artifacts, e.g., acute reactions to the insertion of a needle or pipette, that may influence immediate measurements of interstitial fluid pressures. On the other hand, their long duration introduces the possibility of slower reactions to foreign bodies, including

local changes of pressure from contraction of fibrin strands or of newly formed connective tissue. It may be, too, as Guyton suggests, that the negative pressures result in part from intermittent evacuation of lymphatics by the mechanical pumping which accompanies movement.

Again, the kidney has proved to be a special case. Gottschalk (123) found interstitial fluid pressures averaging +10 mm Hg in rats, guinea pigs, rabbits, and cats, and +16 mm Hg in dogs. These pressures rose promptly whenever renal venous pressure or ureteral pressure was increased. Inside the renal capsule the pressures in tubules, peritubular capillaries, and the interstitium changed together, and by approximately equal increments, without evidence of the breaking pressure found by McMaster (237) in skin and subcutaneous tissue. It seems clear that interstitial fluid pressure, like capillary blood pressure, must be considered tissue by tissue.

5. PROTEINS IN EXTRACAPILLARY FLUIDS; Π_{if}

A. Capillary Filtrate From Limb Capillaries; Protein Content

The concentration of protein in the fluid which is filtered through the capillary wall is an important figure for several reasons. In the first place, it is the most direct measure of capillary permeability to protein, and hence of the effectiveness of the capillary wall as a protein-retaining membrane. Second, this original capillary filtrate is the raw material from which interstitial fluid, and eventually lymph, are produced. Third, just as filtration is produced by $P_c - P_{if}$, so absorption is produced by $\Pi_{pl} - \Pi_{if}$, i.e., by the effective osmotic pressure of the plasma proteins. Fourth, studies on the volumes and protein concentrations of capillary filtrates in various tissues, and under various conditions, have established the existence and approximate magnitude of a physiologically important circulation of protein from capillary blood, through the interstitial fluid compartment around the tissue cells, thence to the lymphatics, lymph nodes and via the lymphatic trunks back to the circulatory system.

By 1898 large regional differences in the concentration of protein in lymph were well known, and corresponding differences in the permeability of capillary walls to protein were postulated. Thus Starling wrote: "The lymph in the limbs, the filtrate through the impermeable limb capillaries, contains only from 2 to 3 per cent proteids; that from the intestines contains

from 4 to 6 per cent proteids; while that from the permeable capillaries of the liver contains from 6 to 8 per cent proteids—in fact almost as much as the blood plasma itself" (346). Over half a century of work on lymph has confirmed these figures, providing some allowance is made for improved analytic methods. In the most recent compilations (79, 386) the total protein in lymph from legs at rest ranged from 1.3 to 3.3 g per 100 ml; from intestine, 2.8 to 4.0, and from liver, 4.4 to 6.1. However, the interpretation of these figures, particularly with respect to the lymph from the limbs, has changed. Starling (346) and also Drinker & Yoffey (79) believed that the protein content of lymph and of interstitial fluid must be identical, a view that now is not tenable. Hence it is helpful to consider in sequence *a*) the protein content of the original capillary filtrate, *b*) the fate of this protein as the capillaries absorb fluid, *c*) the resulting protein content of interstitial fluid, and, finally, *d*) the protein content of lymph. For reasons already described in the previous section it has so far proved impossible to collect normal capillary filtrate directly. However, for limb capillaries relatively consistent estimates of the protein content of capillary filtrate have been obtained indirectly *a*) from analyses of certain edema fluids, *b*) from studies of plasma proteins during venous congestion, and *c*) from studies of lymph during venous congestion and during chronic plasmapheresis.

In severe hypoproteinemic edemas, e.g., nephrosis, malnutrition, and amyloid disease, absorption is presumably abolished because of the lowered osmotic pressure of the plasma proteins. Hence, as previously reviewed (207), the presence in these edema fluids of 0.09 to 0.40 per cent of protein, with most values between 0.1 and 0.27 per cent, provided the first estimates of the protein content of capillary filtrate with the reservation, however, that disease may have modified the permeability of the capillary walls. In cardiac failure, edema fluids contained from 0.1 to 1.0 per cent protein with an average of 0.4 per cent.

In normal subjects, elevating venous pressure to 25 mm Hg or more, i.e., to exceed the osmotic pressure of the plasma proteins, also abolishes absorption of fluid. Landis *et al.* (211) congested the forearms of human subjects and computed from the hematocrit ratios of venous blood the volume of filtrate from each 100 ml blood plasma, and divided this into the amount of protein simultaneously lost from the plasma during the same congestion. The errors involved in small filtered volumes, and even in triplicate protein analyses, prevented any conclusions with congestions of 40 mm Hg; but at 60 mm Hg the calcu-

lated average protein content of the filtrate was about 0.3 g per 100 ml of filtrate, though with very wide variations. At a venous pressure of 80 mm Hg the average protein content of capillary filtrate was 1.5 g per 100 ml, but this was attributed to leakage because of marked vascular distention and slowed blood flow with possible increased permeability from local hypoxia. Fractionation studies of plasma proteins before and after congestion indicated qualitatively that capillary filtrate contained both albumin and globulin. All that this approach could provide, however, was a rough order of magnitude for the normal protein content of capillary filtrate. It indicated merely that it was, on the average, considerably less than the protein content of lymph. In passing, it should be emphasized that this venous congestion method is of doubtful utility in measuring capillary permeability to protein in individual patients with various diseases (e.g., 6, 32, 33) because normal values vary greatly from subject to subject even under carefully controlled conditions (17, 211). The reasons for this variability are still not clear. Probable factors are streamline flow in veins with sampling errors and, in addition, analytic errors even with triplicate hematocrits and protein analyses.

Shortly after the studies of Landis *et al.* (211), White *et al.* (379) approached the problem more directly and found that venous congestion of the dog's leg reduced the concentration of protein in lymph from 0.77 per cent to 0.21 per cent while the rate of lymph production increased sixfold, as would be expected with exclusion of absorption. In another experiment lymph protein fell during venous congestion from 1.24 per cent to 0.78, but lymph flow failed to increase as much as in the previous experiment, and the lymph contained a considerable number of erythrocytes. By still another method Pappenheimer & Soto-Rivera (282) found in the perfused hind limbs of cats that capillary filtrate contained an average of 0.3 per cent protein with values of 0.2 and 0.4 per cent falling within the range of error.

Thus, in mechanical, i.e., noninflammatory, edemas and in congestion of the human forearm, the capillary walls were found to be approximately 95 per cent effective as protein-retaining membranes (207). During rapid filtration the protein concentration of capillary filtrates is extremely small even in the more permeable capillaries of the intestine (168a). It is probable that under these conditions the protein concentration is reduced by molecular sieving as discussed in sections 7D and 10.

Concerning the fate of the protein that has passed from the blood stream with capillary filtrate into the

interstitial fluid compartment, information is far from complete though generally in favor of minimal re-entry into capillary blood despite absorption of fluid. Lewis (215) injected horse serum subcutaneously in dogs and detected it in thoracic duct lymph within 40 min., but in blood only after 3.5 hours. Field & Drinker (97) also injected horse serum subcutaneously into dogs and found, by a precipitin reaction, that when all possible lymphatics were blocked no foreign serum could be detected in the blood stream in periods up to 7 hours after injection. They concluded that the blood capillaries of the subcutaneous tissues are not ordinarily concerned in the absorption of protein. Courtice *et al.* (56, 58, 59) injected plasma protein labeled with T-1824, into the peritoneal cavity and recovered nearly all of it in lymph. Jepson *et al.* (167) followed the removal from skin of protein labeled with I^{131} and in normal dogs found that lymph exhibited far more radioactivity than blood plasma. From similar studies in man, Hollander *et al.* (159) concluded that protein is returned to the circulation chiefly or exclusively by lymphatic flow. In the lung of dogs, however, Drinker *et al.* (78) found that protein injected into the alveoli appeared first in blood though very slowly and in small amount.

It seems likely that most of the protein in capillary filtrate normally fails to enter capillary blood, even during absorption of fluid, because such direct return to plasma involves the movement of protein molecules against a considerable concentration gradient. More information is needed because the mechanism and completeness of this exclusion of protein during absorption of fluid is still far from clear, particularly in abnormal states. Thus, Field & Drinker (98) found in dogs with ligated lymphatics that acute plasmapheresis increased the absorption of foreign protein from the tissue spaces. Jepson *et al.* (167) found this true of labeled protein in lymphedema also.

B. Interstitial Fluid; Protein Content and Π_{if}

The protein content of interstitial fluid under normal, resting conditions, and the protein osmotic pressure of that fluid, Π_{if} , have also been determined so far only by indirect methods. The protein concentration in capillary filtrate being 0.2 to 0.4 g per 100 ml, and that in lymph from a resting extremity being 1.3 to 3.3 g per 100 ml it follows that the protein content of interstitial fluid under resting conditions lies between these figures and is not uniform. Depending upon localized filtration or absorption, it can range from protein-poor capillary filtrate, just produced, to an interstitial fluid which is protein rich

at the end of absorption and about to enter the lymphatic system. Pappenheimer & Soto-Rivera (282) have pointed out that the diffusion coefficients of the plasma proteins are such that in the absence of flow or mechanical movement relatively large concentration gradients are possible in the interstitial fluid compartment. "Even if all filtration and absorption processes were stopped, some 20 minutes would be required to reach 90 per cent equalization of protein concentration over a distance of 50 microns" (282). In perfused limbs of cats the average protein osmotic pressure of interstitial fluid was 1.4 ± 0.4 mm Hg, corresponding to an average protein concentration of 0.7 ± 0.2 g per 100 ml.

The average concentration of proteins in interstitial fluid can also be estimated by a totally different method. The dilution of labeled plasma albumins and globulins after intravenous injection has shown that the total mass of exchangeable plasma protein is about twice the mass of plasma proteins in the blood stream itself (103, 117). Sterling (352) found in man that the average intravascular albumin averaged 117 g, the extracellular albumin, 147 g. Assuming extravascular fluid volume to be the usual 15 per cent of body weight, the average albumin concentration in extravascular fluid was calculated to be 1.4 g per 100 ml. By using Myant's figures (259) to estimate globulin content in addition, the total average protein concentration for extravascular fluid becomes approximately 2.1 g per 100 ml, which corresponds to an average protein osmotic pressure, or Π_{if} , of 5 mm Hg. Similar calculations applied to the data of Wasserman *et al.* (368, 372) yield slightly lower figures, because in the dog the fraction of albumin and globulin found normally in the interstitial fluid and lymph appears to be rather less than that found by Sterling for albumin in man. Both estimates are larger than those given by Pappenheimer and Soto-Rivera (282) for the perfused leg of dogs as expected, because the determinations made by the perfusion method were restricted to the fluid in the immediate vicinity of the capillaries and were limited to the limb, both factors tending to give lower values. On the other hand, calculations based upon exchangeable protein mass include protein in the whole of the interstitial fluid plus that in the lymphatics. In addition, they include the extravascular fluids of the liver and intestines where lymph is known to contain large amounts of protein. Both factors tend to make the figure for average Π_{if} greater for the whole body than for the limb alone, but still not as high as that probably present in the liver and intestines.

With this qualification it can be concluded that Π_{if} lies between 0.1 and 5.0 mm Hg, with the lower value applying to capillary filtrate in the limbs and the higher including the total interstitial fluid of liver and intestines, as well as lymph. This can be compared to P_{if} which ranges from 1 to 9 mm Hg, with the lower values in subcutaneous tissues and skin, the higher values in muscle. The formulation given in equation 1.1 can now, with certain license for purposes of summary, be provided with very approximate values in mm Hg for man at heart level and under resting conditions, viz.:

$$F.M. = k(P_c - \Pi_{pl} - P_{if} + \Pi_{if})$$

| | | | | |
|-------------------------|----|----|--------|----------|
| $+ = \text{filtration}$ | 32 | 25 | 1 to 9 | 0.1 to 5 |
| $- = \text{absorption}$ | 15 | | | |

With equal or greater license an average limb capillary and lymphatic can be drawn, as in figure 5.1, to summarize the filtration-absorption process as it may operate to produce a small volume of lymph with relatively high protein content. Table 5.1 provides a schematic summary of the changes that occur in the fluids of the limb during several of the more thoroughly studied functional states. Ranges of determined values are given whenever possible. Figures in parentheses are values that can reasonably be inferred on the basis of available evidence. They are given merely to show the probable direction of presumed change and its order of magnitude. In some instances even inferences are impossible, as indicated by a question mark. The columns are given letters to correspond with the schematic capillary in figure 5.1.

Beginning at the top of the table with control conditions and resting blood flow, the composition of capillary filtrate has not been determined, but its protein content may be inferred to be 0.2 to 0.4 g per 100 ml from the composition of capillary filtrate produced during mild venous congestion in man and dog. The average protein content of interstitial fluid ranges from 0.7 g per 100 ml in perfusion studies (281) to 2.1 g per 100 ml by calculation from extravascular protein mass. Lymph protein content range from 1.3 to 3.3 g per 100 ml (386) and the volume flow is small, requiring massage or passive movement for collection of samples (76) as would be expected with the absorption that occurs under resting conditions.

Conversely, in venous congestion the protein concentration in capillary filtrate is known but the average and highest concentrations in interstitial

FIG. 5.1. Schematic diagram of "an average limb capillary" to indicate approximate protein concentrations in capillary filtrate, interstitial fluid, and lymph.

TABLE 5.1. Protein Concentrations in Extravascular Fluids of the Limb

| Condition | Capillary Filtrate a | Interstitial Fluid | | Lymph d |
|-------------------|-------------------------|--------------------|--------------------|------------|
| | | Avg conc. b | Highest conc. c | |
| | g/100 ml | g/100 ml | g/100 ml | g/100 ml |
| Normal, resting | (0.2-0.4) | 0.7-2.1 | (1.3-3.3) | 1.3-3.3 |
| Venous congestion | 0.2-0.4 | (0.2-0.4) | (0.2-0.8) | 0.2-0.8 |
| Hypoproteinemia | (0.01-0.4) | 0.04-0.5 | (0.01-0.6) | 0.01-0.6 |
| Burns | (3.5-5.0) | (3.5-5.0) | (3.5-5.0) | 3.5-5.0 |
| Muscular activity | ? | ? | (0.5-1.5) | 0.5-1.5 |
| Lymphedema | ? | 1.9-3.5 | ? | 2.3-3.4 |

fluid have to be inferred from studies on lymph. This inference is valid after newly formed capillary filtrate has washed out of the interstitial compartment the fluid which was present before congestion and while the interstitial fluid compartment is being constantly irrigated by newly formed capillary filtrate with no absorption possible.

Hypoproteinemia in man, as mentioned above, produces edema fluids with protein concentrations ranging from 0.09 to 0.40 per cent. Weech *et al.* (374) used chronic plasmapheresis to produce severe edema of this type in dogs. Edema fluid contained between 0.04 and 0.4 g protein per 100 ml with all but a few values below 0.25. Lymph protein in the same ani-

mals ranged from 0.01 to 0.6, with almost all values below 0.3. In some instances the protein content of edema fluid was slightly higher than that of lymph collected simultaneously, indicating again the possibility of imperfect mixing of the interstitial fluid compartment and, consequently, some sequestration of edema fluid. Capillary filtrate, however, has not been studied and so its protein content can only be inferred. Lessened permeability to protein has been suggested (374) but not proved so far. Sieving of protein molecules may be involved (see section 10).

Massive injury in burns, produced by immersing the extremities of anesthetized dogs in hot water (48, 99, 100, 119, 120) increases lymph flow conspicuously and increases the protein in lymph to between 3.5 and 5 g per 100 ml. In view of the known effects of injury on capillary permeability to protein (200) it is safe to infer that protein concentrations in capillary filtrate and interstitial fluid are equally high; particularly because lymph flow is rapid and the interstitial compartment is well irrigated by capillary filtrate.

For contracting muscle, information is still meager. White *et al.* (379) found in dogs that while the flow of lymph was much increased by exercise, its protein content declined to between 0.5 and 1.5 per cent, average 1.0, and then remained constant as long as exercise continued. The elevations of capillary blood pressure and of interstitial fluid pressure during exercise have already been described in sections 2D and 4. Inferences concerning capillary filtrate and interstitial fluid are unjustified because the lymph col-

lected during exercise (379) contains more erythrocytes than control lymph does. This finding suggests mechanical rupture of some capillaries, probably when compressed between adjacent contracting fibers. If this occurs, undetermined amounts of whole plasma may accompany the erythrocytes and contribute to the protein found in lymph. The possibility of osmotic shifts of fluid produced by small molecules, e.g., lactic acid, from contracting muscle has also been proposed (207).

Finally, in lymphedema, the effect of obliterating lymph flow by obstructive fibrosis of the larger lymphatic vessels (77) is an accumulation of extravascular fluid with abnormally high concentrations of protein in both the edema fluid as well as in the stagnant lymph. The protein content of capillary filtrate is unknown and may be quite variable because of the tendency in lymph stasis toward intermittent infection and consequent injury to capillaries in severely lymphedematous extremities (77). It is clear that more information is needed in all these conditions.

C. Circulation of Interstitial Fluid; Circulation of Protein

It has been customary in the past to say that capillaries "leak" protein as if this were a useless defect of the capillary wall. However, many lines of evidence indicate that passage of plasma proteins through the capillary wall is quite as important for cellular metabolism and for defense against infection as the retention of plasma protein is for normal fluid balance. Whipple & Madden (376) showed that the circulating plasma proteins within the blood vessels form a "medium of exchange" which is an important part of a larger nutritional pool. For example, dogs were maintained in full nitrogen equilibrium by intravenous administration of dog plasma only. Drinker (75) called attention to the benefits derived, during infection, from the passage of globulins, including antibodies, through the capillary wall into the interstitial fluid around the cells and thence to the lymphatics. Still more recently several reviews have described the binding of hormones (63, 304), fatty acids (109), and drugs (121) to plasma proteins. It is significant, too, that the greatest passage of protein through the capillary walls occurs in the liver, where metabolic requirements are greatest and most varied, and where albumin is synthesized.

Two paracapillary circulations (i.e., beside and beyond the capillaries) can be identified. The first is a

filtration-absorption circulation which includes the total capillary filtrate, the total interstitial fluid, and finally that part of the interstitial fluid which passes back into the capillary blood by the process of absorption. The second paracapillary circulation begins also with capillary filtrate but then reduces to the unabsorbed fraction of interstitial fluid and its contained protein, both of which, after bathing the tissue cells, enter the finest lymphatic capillaries and are conducted, via the major lymphatic trunks, back to venous blood (see Chapter 30). Enough information is available now to justify approximate calculations of the magnitudes of these two circulations. Because both depend upon the total volume of capillary filtrate this figure can be considered first.

Continued blood flow through the resistance of the capillaries requires, even at resting flow rates, a significant pressure gradient in the capillary bed itself. As indicated in table 2.1 and figure 2.3 this average gradient lies above the osmotic pressure of the plasma proteins in the first half of the capillary network. It follows that, secondary to the basal pressure head which is necessary for this resting blood flow, there is necessarily a "basal filtration" of fluid under resting conditions. Most of this filtrate is absorbed and the low rates of lymph production in resting extremities can give no indication of the rate at which the original capillary filtrate is formed. A simple calculation suggests, however, that in the resting animal capillary filtrate is continuously produced at an average rate which is at least five to ten times greater than average resting lymph flow.

Landis & Gibbon (209) found in the human forearm at 34 to 35 C that elevating venous pressure by 1 cm H₂O increased filtrate by .0033 ml per 100 ml forearm tissue per min. Assuming that 80 per cent of a rise in venous pressure is transmitted to the capillaries, this becomes .0040 ml per 100 ml forearm tissue per min for a 1 cm water increase of capillary pressure. From capillary pressure measurements in human skin, mean resting filtering pressure is $(32 - 25 \text{ mm Hg})/2$ or 3.5 mm Hg, or 4.8 cm H₂O. Assuming, for the purpose of obtaining a minimum figure, that the unit increment of filtration given above applies to the whole body, the total resting capillary filtrate for a 75-kg human being is approximately 20 liters per 24 hours. To the extent that filtration coefficients in liver and intestine may be greater than in the forearm the volume of filtrate formed per 24 hours will be somewhat larger still.

For total lymph flow in man the most helpful data are those of Crandall *et al.* (60) obtained from a

patient with a freely draining fistula of the thoracic duct. Average basal lymph flow during fasting was 0.93 ml per min. After a heavy meal, flow from the thoracic duct reached a peak volume of 3.9 ml per min and remained above 1.0 ml per min for several hours. If allowance is made for the additional and uncollected lymph from the right lymphatic duct by adding an increment of one-fourth to one-third of fasting thoracic duct flow, then total lymph flow in fasting man at rest is approximately 2 liters per 24 hours. With allowance made for the effects of meals and activity, it probably approaches 3 or 4 liters per 24 hours.

Figure 5.2 shows schematically the volumes of these several "circulations" in terms of exchanges in 24 hours. With a cardiac output of 6.0 liters per min the first circulation, that of blood itself, amounts to about 8000 liters per 24 hours. From this volume, filtration in the capillary bed removes a minimum of 20 liters per 24 hours, a "filtration fraction" of 0.25 per cent. This capillary filtrate begins the second circulation, that of interstitial fluid (fig. 5.2, F to IF to A) with capillary absorption, during rest, of 80 to 90 per cent or 16 to 18 liters, of the original capillary

filtrate. The remaining 2 to 4 liters, including the unabsorbed protein of the original capillary filtrate, then produces the third circulation, that of proteins in lymph.

The potential magnitude of this protein circulation can be estimated from the observations of Wasserman & Mayerson (370-372) on the rates at which intravenously injected labeled albumin and globulin disappeared from plasma and appeared in thoracic duct lymph. The faster component of these two-phase disappearance curves indicated a steady disappearance of plasma albumin from plasma, and corresponding appearance in lymph, at the rate of approximately 0.1 per cent of the total circulating plasma protein per minute. Allowing for the slightly slower disappearance rate of globulin (372), this amounts to the passage through the capillary wall in 24 hours of a mass of plasma protein approximately equal to that in the circulating blood itself. This includes passage from the more permeable hepatic and intestinal capillaries as well as from the less permeable limb capillaries. Courtois (49; 386, p. 87) collected lymph simultaneously from the thoracic, right lymphatic, cervical, foreleg, and hind leg ducts. Expressed as percentage of total intravascular protein, the lymph collected from these several sources contained a 24-hour protein mass equaling, respectively, 47.5, 3.6, 2.4, 2.2, and 1.8 or, in total, 57.5 per cent of the intravascular protein mass. Again this rate of passage is a basal rate found in resting animals. Intravenous infusions increased the rate of protein passage severalfold (371) and increased lymph flow from the thoracic duct correspondingly (180), indicating that the interstitial circulation of both protein and fluid can be very rapid indeed. Studies during muscular exercise would be most interesting, but have not been done so far.

For man the magnitude of this protein circulation can be estimated in two ways. First, the obligatory capillary filtrate of 20 liters per 24 hours, containing 0.2 to 0.4 g per cent protein, would carry with it a minimum of 40 to 80 g of protein per 24 hours. This figure is unquestionably too low because it does not include the higher protein content of capillary filtrates from liver and intestine. Second, collections of thoracic duct lymph with analyses of protein content have been carried out in two patients with accidental fistulae (57, 60) and in patients with terminal neoplasm (15). As mentioned above, the data of Crandall *et al.* (60) justify an estimate of 2 to 4 liters of lymph per 24 hours. Since the protein content of this lymph ranged from 3.19 to 4.88 g per 100 ml the circulation

FIG. 5.2. Diagram of the "several circulations" with approximate magnitudes of each. For explanation of diffusion exchanges see section 9. For explanation of figures relating to filtration, absorption, and lymph flow see text of this section.

of protein can range from 60 to 200 g per 24 hours, depending upon conditions. Hence the third, or protein, circulation passing from capillaries to interstitial fluid to lymph (fig. 5.2, F-IF-L) involves daily a volume of fluid which approaches the volume of circulating plasma and a mass of protein equivalent to a quarter or more of the mass of the circulating plasma proteins. Cope & Litwin (45a) have recently emphasized the compensatory importance, during recovery from hemorrhage, of this continuing flow of lymph and its contained protein from the interstitial spaces into the blood stream.

6. FILTRATION COEFFICIENTS OF CAPILLARIES (k_c); AND OF TISSUES (k_t)

A. Normal Capillaries

Measurements of fluid movement through the capillary wall as a function of hydrostatic and osmotic pressures have been made in single capillaries of amphibian mesenteries (23, 200, 201, 383); in the human forearm (24, 188, 209); in the perfused extremities of frogs (61, 74); of rats (162, 302); of cats and dogs (281, 282); and in lung (132).

The primary measurements necessary to test the validity of the Starling hypothesis were first obtained by micromanipulation techniques in single capillaries of the frog's mesentery (200, 201) with results shown

FIG. 6.1. Relation between fluid movement through walls of single capillaries of frog's mesentery and capillary blood pressure as determined by micromanipulation methods. Slope of line indicates filtration coefficient (k_c) in μ^3 of fluid filtered (or absorbed)/sec/ μ^2 of capillary wall/cm H_2O capillary pressure. Intercept of line with zero axis measures effective osmotic pressure (in vivo) of the plasma protein. [From Landis (200).]

in figure 6.1. When capillary pressure exceeded 12 cm water, fluid passed from the plasma inside the capillary to outside the capillary (filtration). When capillary pressure was less than 10 cm water, fluid was withdrawn from the extravascular space into the capillary (absorption). At capillary pressures between 9 and 13 cm water there were many instances in which little or no movement of fluid occurred. In this range hydrostatic pressure was apparently balanced by the osmotic pressure of the plasma proteins. This was taken to be indirect evidence that the walls of the mesenteric capillaries of the frog were relatively impermeable to protein and that, at least in these vessels, 9 to 13 cm water (average 11.5 cm) represented the effective osmotic pressure of the plasma proteins in vivo.

In addition to supporting the filtration-absorption hypothesis of Starling these results also provided the first measure of the permeability of the capillary wall to isotonic fluid. When plotted against capillary pressure the rates of fluid movement were directly proportional to the difference between the capillary pressure and the effective osmotic pressure of the plasma proteins measured against the capillary wall as a filter. The proportionality constant was computed from the slope of the straight line drawn through the observed points by the method of least squares. This was originally called a "filtration constant," but for reasons given below the term "filtration coefficient" is preferable (276). For normal mesenteric capillaries of the frog the filtration coefficient, k_c , derived from 70 observations, averaged $.0056 \mu^3$ of fluid per sec per μ^2 of capillary wall per cm water difference between capillary pressure and the osmotic pressure of the plasma proteins. Wind (383) found great variation from capillary to capillary in the toad's mesentery. Collectively, these figures provide a slightly lower average figure, about .0032, during the first 15 min after the mesentery was exposed and a somewhat higher average figure, .0084, thereafter. Deviations from these normal filtration coefficients have proved helpful, as will be described below, in measuring the effects of temperature (23), oxygen lack (201), and injury (200) on the filtration-absorption mechanism in the frog's mesenteric capillaries.

To test the validity of the Starling hypothesis in another tissue, and particularly in man, Krogh *et al.* (188) studied the movement of fluid through the capillary walls of forearm tissue in a pressure plethysmograph, by means of which the blood vessels could be collapsed in order to measure small increments of tissue volume produced by filtered fluid. As shown in

figure 6.2 net filtration of fluid increased linearly with venous pressures above 10 cm water. A unit rise of venous pressure (1 cm water) increased the filtration rate by .0023 ml per min per 100 ml of forearm tissue when congestion periods of 30 min were used (188) and by .0033 ml per min per 100 ml forearm tissue when congestion periods of 10 min were used (209). As described in section 4, this difference was regarded as the result of increasing interstitial fluid pressure as the volume of filtrate in the tissues increased.

Brown *et al.* (22) have more recently studied, by a totally different method, the filtration coefficient for the whole body of man (except the thorax) during a systemic rise of venous pressure produced by repeated Valsalva maneuvers. Though results varied slightly, depending on the method of calculation, representative filtration coefficients for the whole body were in the first 9.5 min, .0036 ml per min per 100 g body wt per cm rise of venous pressure and, for a total of 29.5 min, .0014. These values can be compared to .0033 and .0023 for the forearm alone. The two sets

FIG. 6.2. Rates of filtration measured by pressure plethysmograph in human forearm during graded elevation of venous pressure for 10-min periods. Plethysmograph temperature, 34–35 C. The slope of the line corresponds to a filtration coefficient (k_f) of .0033 ml/min/100 ml forearm tissue per cm H_2O increase of venous pressure. [From Landis & Gibbon (209).]

of figures are similar, presumably because the collective capillary beds of muscle and subcutaneous tissue are large compared to the smaller, though more permeable, capillary beds of liver and intestine. A similar relationship has been found with respect to diffusion (see section 8). The “whole body” filtration rate appears to decline more rapidly than that of the forearm, owing probably to more rapid return of capillary filtrate by way of the lymphatics, particularly during the vigorous respiratory movements required for repeated, brief Valsalva maneuvers.

Landis & Hortenstine (210) calculated from the forearm filtration figures (188, 209) that a rise of venous pressure, throughout the body, to 10 cm water above normal might, in a man weighing 75 kg, filter as much as 250 ml of fluid from the plasma in the first 10 min. This has proved a fairly good estimate. Brown *et al.* (22) observed the filtration of 333 ml to 501 ml when systemic venous pressure was elevated by 20 cm for 9.5 min. Over 29.5 min an increase of venous pressure by 20 cm water filtered 460, 417, and 687 ml of fluid, calculated to contain between 1 and 2 g of protein per 100 ml owing, presumably, in part to the very high protein content of capillary filtrate from hepatic and intestinal capillaries.

The pressure plethysmograph was used by Krogh *et al.* (188) also to test the effect on filtration rate of changing the osmotic pressure of the plasma proteins. Filtration rates at given venous pressures were measured with the subject recumbent and then at the same venous pressures while the subject stood quietly on a tilt table for 30 min or more. Quiet standing increased the concentration of the circulating plasma proteins by 0.6 to 1.1 g per 100 ml and the protein osmotic pressure of plasma by 3.3 to 8.7 cm water. At these higher protein osmotic pressures the rate of filtration produced by a given venous pressure was always lower. A unit rise of protein osmotic pressure (1 cm water) was accompanied by a reduction of filtration rate ranging from .0027 to .0045 ml per min per 100 ml forearm tissue. These values were quantitatively similar to the effect produced by elevating venous pressure by 1 cm water, but opposite in sign. Within the limitations of the method these results justified extending the Starling hypothesis to the forearm capillaries of man, and were compatible with the view that the capillaries of the human forearm were relatively impermeable to the plasma proteins.

In the first studies with the pressure plethysmograph (188, 209) it was perplexing to find that venous

FIG. 6.3. Relation of net fluid movement in perfused hind leg of cat to difference between the mean hydrostatic pressure in the capillaries (p_c) and the sum of all pressures opposing filtration (isogravimetric capillary pressure, p_{ci}). The slope of the line corresponds to a filtration coefficient (k_t) of 0.014 ml/min/100 g tissue/mm Hg pressure difference. [From Pappenheimer & Soto-Rivera (282).]

pressure had to be elevated by 10 to 17 cm water before net filtration could be detected (fig. 6.2). Brown *et al.* (24) showed later, however, that the regression lines relating filtration and venous pressure passed through zero, provided *a*) that interstitial fluid was carefully evacuated from the forearm prior to congestion, and *b*) that a correction was made for the volume of interstitial fluid pressed out of the forearm segment during each volume measurement.

From regression lines such as the one shown in figure 6.2 it is possible to calculate an approximate filtration coefficient (k_t) for forearm tissue if allowance is made for the fact that a given elevation of venous pressure produces a somewhat smaller elevation of mean capillary pressure. On the assumption that the latter is 80 per cent of the former, k_t for human forearm capillaries becomes approximately .0057 ml per min per 100 g tissue per mm Hg as given in table 6.2. The filtration coefficient for the whole body becomes .0061.

Among the several perfusion methods that have been used to measure filtration coefficients, the most precise and revealing is the isogravimetric technique developed by Pappenheimer & Soto-Rivera (282) in which filtration and absorption were identified by changes in weight of an isolated limb. Arterial pressure, venous pressure, osmotic pressure of the perfusing fluid, blood flow, and temperature could be varied at will and their influence on the filtration-

absorption equilibrium could be measured separately. A detectable effect on fluid movement resulted from a change of venous pressure by 0.5 mm Hg and sometimes less, or from a change of arterial pressure by 2 to 4 mm Hg. Capillary pressure was 5 to 10 times more sensitive to a change of venous pressure than to a change of arterial pressure.

Figure 6.3 shows net fluid movement, i.e., filtration or absorption, plotted against the difference in pressure across the capillary membranes themselves. Filtration and absorption were proportional to the difference between the calculated mean capillary blood pressure and the isogravimetric capillary pressure which is, by definition in this method, the sum of all pressures opposing filtration. In figure 6.3 the slope of the regression line indicates a filtration coefficient of .0105 ml per 100 g tissue per min per mm Hg change of capillary blood pressure. The filtration coefficient was independent of the absolute value of the isogravimetric capillary pressure when this was varied by diluting or concentrating the proteins in the perfusing fluid. Similar methods have been applied recently by Renkin & Zaun (302) to the hind legs of the rat.

The constancy of filtration coefficients at high and low capillary blood pressures (figs. 6.1, 6.2, 6.3) suggest that under these conditions capillary surface area and capillary porosity are not significantly modified by pressure. This may be related to the con-

clusions reached by Burton (31) that vessels of small diameter are relatively indistensible. Under more severe conditions and in other tissues, however, the permeability of the capillary walls may be increased when capillary blood pressures are very high (211) or when blood volume is much increased (131, 331, 361, 369).

In all the regions so far considered, resting average capillary blood pressure is approximately equal to the osmotic pressure of the plasma proteins. In the lung, however, as described in section 2, average capillary pressure is only 5 to 10 mm Hg and therefore less than half the osmotic pressure of the plasma proteins. Figure 6.4 shows the rate of edema formation in the lungs of dogs plotted against left atrial pressure (132). In contrast to other tissues, net filtration and increase of interstitial fluid volume were not observed until, at atrial pressures of 25 to 30 mm Hg, pulmonary capillary pressure began to exceed the protein osmotic pressure of 25 mm Hg. Thereafter filtration increased linearly with left atrial pressure at a rate of 0.21 g of fluid per hour per mm Hg per g dry wt of lung tissue or 0.065 g per min per mm Hg per 100 g wet lung tissue. The relative "dryness" of lung tissue which is produced by a low capillary pressure is indicated by the absence of filtration between atrial pressures 0 and 23 mm Hg. This margin of dryness was reduced to half normal when the plasma protein concentration was decreased by plasmapheresis to an average of 47 per cent of the control protein concentration. Taken together, the

results shown in figures 6.1 to 6.4 permit concluding that in these four regions the net rates of filtration or absorption through the capillary walls depend upon the difference between hydrostatic and osmotic forces acting across the membrane. In view of this evidence the Starling hypothesis of 1896 (345) can fittingly be called now the Starling filtration-absorption principle.

Progress has gone beyond this qualitative stage, however, because the meaning of k , the filtration coefficient, has been expanded not only by numerical values for a number of capillary beds and membranes (tables 6.1 and 6.2) but also by more precise definition. Pappenheimer (276) called attention to the fact that the several different "filtration constants," "unit filtration rates," or "filtration coefficients" used by various authors can be related to the equation used by Darcy (62) to describe the viscous flow of fluids through inert porous or fibrous materials, viz.:

$$\dot{Q}_f = \frac{k A_m \Delta P}{\eta \Delta x} \quad (6.1)$$

where

\dot{Q}_f = quantity filtered per unit time

k = specific filtration constant of the porous material or membrane

A_m = area of membrane

ΔP = pressure difference across membrane (in capillaries $\Delta P = P_c - P_{if} - \Pi_{pl} + \Pi_{if}$)

Δx = path length through membrane (for capillaries usually assumed to be 0.3μ)

η = viscosity of filtrate

FIG. 6.4. Rate of edema formation (filtration) in lungs of dogs subjected to prolonged elevations of left atrial pressure. Significant filtration did not appear until left atrial pressure exceeded 25 mm Hg, i.e., the osmotic pressure of the plasma proteins. [From Guyton & Lindsey (132).]

If the area of capillary wall can be measured directly (23, 200, 201, 383) or computed (281, 282) as in table 6.1, the proportionality factor or filtration coefficient consists of $k/\eta\Delta x$ including the Darcy "specific filtration constant," the thickness of the wall, and viscosity of the fluid. On the other hand, for tissues in which the capillary surface per weight or volume of tissue is not yet known precisely, e.g., in the human forearm, the hind quarters of the rat, and the lung, the proportionality factor for unit tissue weight or volume will consist of $kA_c/\eta\Delta x$ including, in addition, the area of the capillary walls, A_c . The term "filtration constant" is certainly inappropriate and should be abandoned for a membrane system as heterogeneous as that in the capillary wall. Filtration coefficient is a preferable term and it is suggested that the symbol k_c be used for cases where the area of capillary wall is measured or computed and k_t be used for coefficients based on mass or volume of tissue. Newer developments in pore theory have led

Pappenheimer (276) to suggest also that the term "capillary permeability" be reserved for describing the properties of the capillary wall with reference to the diffusion of small molecules. Filtration coefficients, because they deal with flow of fluid through a membrane, would then be a measure of hydraulic or hydrodynamic conductivity of the capillary wall.

Table 6.1 is taken from the review by Renkin & Pappenheimer (301) with inclusion of some more recent values. It compares filtration coefficients of cell membranes (upper section), of capillary walls (middle section), and of certain artificial membranes (lower section). Cell membranes have smaller filtration coefficients than capillaries, although the difference between the values for the erythrocyte and the mammalian muscle capillary is small. The range of filtration coefficients for capillary walls is very large, amounting to a 200-fold difference in the mammal between muscle capillaries and glomerular capillaries. The coefficients for artificial membranes, calculated for comparable thickness, are in turn much higher still and, with other evidence, led Pappenheimer *et al.* (281) to the conclusion that the collective area of the pores involved in the filtration process is only a small fraction of the total capillary surface. Support for this conclusion came from measurements of capillary permeability to small lipid-insoluble molecules, and will be given in sections 8 to 10.

Table 6.2 compares average filtration coefficients (k_t) for extremities of four species. In the forearm of

man, on the assumption that capillary pressure is increased by 80 per cent of given increases in venous pressure, the average filtration coefficient becomes .0057 ml per min per mm Hg per 100 g tissue. From the data of Brown *et al.* (22) k_t for the whole body is .0061. In smaller animals progressively larger filtration coefficients are found. As Renkin & Pappenheimer suggest (301), this relationship is teleologically fitting because the smaller the mammal, the more active are its metabolic processes and therefore the greater will be the requirement for a more extensive capillary bed (320) and for more rapid exchanges between blood and tissue. To obtain comparable filtration coefficients for other tissues, e.g., liver, intestine, lung, and brain, is far more difficult. Values for lung have been published recently by Guyton & Lindsey (132) and for brain, or perhaps chiefly the arachnoidea, by Coulter (47).

B. Effects of Temperature on Filtration Coefficients

As noted above, the Darcy equation indicates that flow through porous materials changes with temperature in inverse proportion to viscosity, and accurate measurements of flow through artificial, porous membranes have confirmed this expectation (16, 81). The filtration coefficients for capillaries, k_c , and for tissues, k_t , include the viscosity of the filtered fluid and should change with temperature. This was found to be clearly the case by Pappenheimer (277) in the perfused limb in which the capillary membranes retain their normal impermeability to plasma proteins over a temperature range of 8 to 44 C. The ratio of the filtration coefficient measured at 36 ± 2 C to that measured at 10 ± 2 C averaged 1.68 ($SE = \pm 0.08$). This value was within 10 per cent of the ratio of viscosities of water at the two temperatures ($\eta_{10} / \eta_{36} = 1.85$) and the difference between the two ratios was not significant ($P > .05$).

In the frog mesentery Brown & Landis (23) had observed earlier a decrease of filtration coefficient (k_c) from .0070 to .0019 when temperature was reduced from 24 ± 2 C to 0 ± 2 C. However, as mentioned by Pappenheimer (276), the decrease in filtration coefficient was larger than that to be expected theoretically and the scatter of values for individual capillaries was too great for quantitative conclusions.

In the human forearm, Landis & Gibbon (209)

found the filtration coefficient (k_t) almost halved as the temperature of the plethysmograph (and of the superficial tissues of the forearm) was changed from 44 or 45 C to 14 or 15 C. Brown *et al.* (24) extended these observations to 4 to 5 C. Figure 6.5 (heavy line) shows the filtration coefficients observed in the forearm at plethysmograph temperatures over the total range of 44 to 4 C. Using the data of Barcroft & Edholm (9), the figures just above the bottom line of the chart show the probable temperatures in muscle and subcutaneous tissues corresponding to each surface temperature. Starting from the filtration coefficient at a tissue temperature of 35 to 36 C (surface temperature 34 to 35 C) the fainter, dash lines indicate coefficients of filtration calculated on the basis of deep tissue temperature and the corresponding change in viscosity of capillary filtrate. Observed and calculated filtration coefficients agree fairly well at tissue temperatures ranging from 35 to 17 C. Above 35 C the observed coefficient is much higher than the calculated one, indicating that changes other than viscosity are involved. To be considered are such factors as increased capillary pressure and filtering area (8) secondary to vasodilatation or, possibly, opening of arteriovenous anastomoses with elevation of small vein pressure. Below a tissue temperature of 17 C, the observed filtration coefficient does not decrease as it should if viscosity alone were involved, but in-

FIG. 6.5. Effects of temperature on filtration coefficients, k_t , observed in the human forearm (solid line), compared with filtration coefficients to be expected by calculation from change of viscosity of water by reason of temperature changes in muscle (---) and subcutaneous tissue (---) [Calculated from results of Landis & Gibbon (209), Brown *et al.* (24) and, for deep temperatures, Barcroft & Edholm (9).]

creases considerably. Moreover, Brown *et al.* (24) found that even at normal venous pressures cooling the surface of the forearm to 4°C produced a slow but steady increase of the reduced forearm volume presumably because of filtration and augmented interstitial fluid volume. These results suggested "cold injury" of surface capillaries and diminished effective osmotic pressure of the plasma proteins. Passage of protein through the capillary wall in severe cold has been described by Lewis (218), who found up to 3 g per cent of protein in the edema fluid. In summary, it appears that for intact tissues the effects of moderate changes of temperature on filtration coefficients can be explained fairly well by the changing viscosity of capillary filtrate. At very high and very low temperatures other factors, as yet unanalyzed, become more important.

C. Adsorbed Plasma Protein and Filtration Coefficients

The functional dimensions of capillary pores, and hence the filtration coefficients of capillaries, are probably determined in part, by a layer of adsorbed plasma protein. Krogh & Harrop (186) were the first to note that perfusion of extremities with non-protein colloids fails to prevent edema. Their observations were confirmed and extended by Drinker (74), Danielli (61), and Shleser & Freed (332). Kinter & Pappenheimer (cf table 6.3) found that dextrans failed to exert their full osmotic pressure in vivo unless more than 0.2 per cent protein was present in the perfusion fluid. Net filtration usually occurred in dextran-Ringer perfused muscle at all venous pressures; 10 to 20 min after addition of 1 per cent plasma protein the direction of net fluid movement was reversed as the osmotic pressure of the dextran became effective across the capillary walls. The phenomenon was fully reversible and could be repeated several times on the same preparation during the course of a few hours. The capillary filtration coefficient was usually more than doubled when Ringer's solution (295) or Ringer-dextran solutions were substituted for plasma. In nine experiments the filtration coefficient averaged $0.016 \pm .003$ ml per min per 100 g tissue during perfusion with blood, $0.037 \pm .002$ during perfusion with protein-free red cell suspensions, and $0.019 \pm .003$ when protein was restored to the perfusion fluid. The effect appears to be nonspecific, since normal filtration coefficients were found in cat or rat hind limbs perfused with human or bovine serum albumin (295), cat hemoglobin, or bovine hemoglobin (299).

From unpublished experiments of Kinter and Pappenheimer.

The minor axis of serum albumin is about 30 Å and complete removal of albumin from the inside of a pore might increase effective pore radius by this amount. Given a mean pore radius of 45 Å (see sections 9 and 10), the filtration coefficient would be expected to increase by the factor $(30 + 45)^4 \div (45)^4$ or more than sevenfold. A reversible increase of this magnitude was observed in only one preparation, but it is possible that even prolonged washout with protein-free solutions fails to remove all adsorbed protein. The effects of adsorbed protein should be considered, however, in comparing pore dimensions calculated from permeability measurements with pore dimensions observed in electron micrographs.

D. Effects of Injury on Filtration, Absorption, and Filtration Coefficients

CAPILLARY STASIS. Cohnheim in 1867 postulated a "molecular alteration in the vessel walls" and augmented "porousness" to explain the transudation of fluid, protein, and cells in inflammation (42, 43). Since then abundant qualitative evidence has indicated that injury of many types increases the permeability of the capillary wall to fluid and protein (207). Inflammation is, however, an exceedingly complex series of reactions (246, 247, 344), of which increased capillary permeability is only one part. Physiologists have, therefore, tended to study simpler forms of

injury. A few quantitative measurements in terms of filtration coefficients are available and provide estimates of the increased porousness even though information on the "molecular alterations" of the vessel walls is still completely lacking.

In considering the mechanism of simple, chemical injury, Krogh & Harrop (187) in 1921 described "capillary stasis" as direct microscopic evidence of increased permeability of the capillary wall. The steps by which chemical injury leads to capillary stasis merit full description, because capillary pressure, flow, filtration, absorption, and diffusion are all affected. The changes observed in a single, damaged capillary form a unit lesion which helps to explain the effects of more generalized injury.

Blood corpuscles, when first entering a capillary, are clearly separated by plasma. As long as the capillary wall is normal this remains the case and flow continues. Even when capillary blood pressure is high, filtration reduces the volume of plasma in flowing capillary blood very slightly, because the fraction of plasma filtered is normally less than 4 per cent of the plasma volume at most, and usually 1 to 2 per cent. However, as soon as injury is produced, e.g., by applying 25 per cent urethan or 10 per cent alcohol in Ringer's solution, the corpuscles clearly begin to move closer together as they flow along the capillary, because plasma is lost progressively through the now injured capillary wall. Eventually, at the venous end of the capillary, nearly all the plasma having been filtered off, the corpuscles become so closely packed, and collectively so viscous, that they come to a standstill in the capillary and form a localized plug of cells just short of the venule. Meanwhile plasma, with few or many erythrocytes, continues to enter the arteriolar end of the capillary, though much more slowly than before and in a distinctly pulsatile fashion, because entry is now limited by the volume of plasma being filtered through the damaged capillary wall.

The plasma of this blood is also lost by rapid filtration. The additional corpuscles are progressively concentrated in their turn and finally deposited cumulatively on the already existing column of erythrocytes in the venous end of the capillary. Eventually a column of packed cells fills the whole capillary and takes on a characteristic, transparent, bright red color, apparently because the erythrocytes are so closely packed that light rays are no longer refracted as they are when the surfaces of single corpuscles are normally separated by intervening plasma. Flow ceases entirely in capillaries thus filled and plugged.

If injury is severe, capillary stasis is irreversible. If

injury is mild, resumption of flow is frequently observed. The first indication of beginning recovery is the loosening of corpuscles in the packed column, followed by slow, then more rapid, squeezing of the column into the stream of the nearest venous capillary or venule. Here the cells can be seen separating easily in the plasma of the venules as they are carried away. In this respect simple stasis differs from the "sludged" corpuscles described by Knisely *et al.* (176) for more drastic states in which the corpuscles adhere to each other and form minute emboli.

Even after flow has returned some erythrocytes and leukocytes usually remain adherent to the inner surface of the damaged wall, but eventually these, too, float free (199). Platelets may be seen adhering to the wall for still longer periods and probably help restore relative impermeability to protein as suggested by Danielli's perfusion studies (61) in which platelets reduced the rate of edema formation to one-tenth that found with platelet-free perfusion media. Platelet protein, in association with calcium, has also been found to restore normal permeability (381).

Chemical injury of the grade just described increases capillary permeability enough to permit passage of plasma proteins (200), colloidal dyes (107, 152, 184, 199), and colloidal starch (184) but, as observed by light microscope, the walls of true capillaries still retain most of the carbon particles of injected India ink (152, 184, 199). This is true also of localized mechanical injury produced by compressing capillaries with a glass rod (199), or by prodding with a minute needle (37). In these simpler forms of injury gross ruptures of the capillary wall are not present because carbon particles, as well as erythrocytes, are retained as plasma is filtered off.

FILTRATION COEFFICIENTS, k_c , OF INJURED CAPILLARIES.

The permeability of injured capillaries has been measured in the frog's mesentery by determining their filtration coefficient during stasis using the method already described for normal capillaries (200). Figure 6.6 shows filtration rates plotted against capillary blood pressure, injury having been produced by irrigating the mesentery with 10 per cent alcohol or 1:10,000 mercuric chloride in Ringer's fluid. As with the normal capillary wall, filtration increased linearly with capillary blood pressure. Comparison of the regression lines for injured capillaries (above) and normal capillaries (below) indicates, however, that the filtration coefficient was

FIG. 6.6. Effects of severe chemical injury on fluid movement through walls of frog's mesenteric capillaries. Slope of lower regression line shows filtration coefficient, k_c , for normal capillaries. Slope of upper regression line indicates the 7-fold increase of filtration coefficient found after injury. Filled circles refer to injury by 10% alcohol in Ringer's fluid; plus signs, to 1:10,000 mercuric chloride in Ringer's fluid. [From Landis (200).]

increased from the normal value of 0.0056 to approximately $0.0390 \mu^3$ per sec per μ^2 of capillary wall per cm water of capillary pressure, indicating a sevenfold increase of hydrodynamic conductivity. Increased permeability of the injured wall to plasma proteins is indicated by the absence of absorption even at low capillary pressures and by the reduction of the *in vivo* osmotic pressure of the plasma proteins from the normal value of 11 cm water to between 3 and 4 cm water. Thus the effects of severe injury are *a*) increased filtration, *b*) absence of absorption, *c*) reduced effective osmotic pressure of the plasma proteins, and *d*) eventual cessation of flow in any capillary injured to the point of stasis. Diffusion rates have not been measured in such capillaries. Presumably, since capillary permeability to fluid and protein is greater, net diffusion of small molecules should be increased as long as blood flow continues. However, since net diffusion is flow limited, its effectiveness in exchanges of substances will decline as flow decreases and will

soon cease in those capillaries that are filled with stationary, closely packed erythrocytes.

CAPILLARY PRESSURE IN INJURY. The appearance of edema in injured regions is due primarily to increased capillary permeability, but is enhanced by increased capillary blood pressure. Local injury elevates capillary blood pressure by at least two mechanisms: 1) the vasodilatation and increased blood flow which are parts of the triple response to injury described by Lewis (217), and 2) the temporary blockage of capillary blood flow and passive congestion produced by stasis (199).

Application of a minute silver nitrate crystal to the skin of the frog's web increases capillary pressure in the neighborhood of the lesion to peak values which are as much as double the earlier control values (205). Within 10 to 20 min capillary pressure is again within the normal range. In human skin the flare of the triple response produced by histamine is accompanied by peak capillary pressures of 10 to 25 mm Hg above preceding control values (203), but again with relatively prompt return to control values. The onset and duration of these elevations suggest that they are a part of the flare due to the "axon reflex."

Elevations of capillary blood pressure are also found in capillaries injured to the point of stasis. These elevations are more important in the formation of edema fluid during injury because they occur in vessels, the walls of which are permeable to protein and hence already the site of rapid filtration without any balancing absorption. Figure 6.7 shows the cycle of pressure changes which occurred in one experiment involving stasis and recovery. Control capillary blood pressure, with normal blood flow, ranged from 12 to 15 cm water. At the time marked *A* 25 per cent urethan was applied to the mesentery and the onset of stasis, as indicated by visible loss of plasma, was clearly present at *B*. The sharp rise of capillary pressure between *B* and *C* occurred as the venous end of the capillary was filled and blocked by packed erythrocytes. As flow ceased capillary pressure rose rapidly to approach the pressure in the feeding arteriole. At *C* a pressure of 22.5 cm water merely stopped the advance of erythrocytes toward the pipette. Even 30 cm water did not move the corpuscles away so that capillary blood pressure was well in excess of the 22.5 cm water charted. The very rapid filtration observed during this period is due, therefore, to increased permeability and also to high capillary pressure. Between *C* and *D* this enhanced filtration of whole plasma packed erythrocytes

FIG. 6.7. Chart indicating the changes of capillary blood pressure in frog's mesentery during capillary stasis produced by applying 25% urethan solution (A to C) and during recovery with resumption of capillary blood flow (C to D). [From Landis (199).]

tightly throughout the capillary. After D, arteriolar pressure having been blocked by the packing of erythrocytes up to the arteriocalillary junction, capillary blood pressure fell to the level in the venule. This secondary fall of pressure seems to assist recovery from stasis because, as it occurs, one can observe that the erythrocytes become less tightly packed and slow movement toward the nearest venule begins. At D sluggish flow was being resumed. Hence in injury, capillary stasis and the rapid accumulation of relatively large volumes of protein-containing edema fluid or blister fluid depend primarily upon increased permeability, but also upon increased capillary blood pressure. Recovery from stasis, while assisted by temporary lowering of capillary blood pressure, cannot occur until the permeability of the wall to protein returns toward normal.

TISSUE ASPHYXIA; RELATION OF FILTRATION COEFFICIENTS TO O_2 , CO_2 , AND pH. The effects of arrested blood flow and, more specifically, of hypoxia on capillary permeability and the filtration-absorption mechanism are still uncertain. In general, it appears that arrest of blood flow must be total and prolonged, and that hypoxia must be severe, before changes in permeability become demonstrable. Lazarus-Barlow (213) in 1894 studied the edema of passive congestion, and also the edema which appeared when blood flow was restored after a prior period of complete arterial and venous occlusion. He ascribed the latter edema

to functional modification of the vessel walls secondary to "starvation of the tissues" and accumulated waste products. More recently Pochin (285) found in the rabbit's ear that occluding the circulation for 2 hours led to demonstrable edema which appeared shortly after circulation was re-established. Occlusions of 16 to 18 hours produced enough edema fluid to permit collecting samples in which the protein content approached 5 g per cent. Edema alone might conceivably have been the result of vasodilatation and high capillary blood pressure that probably followed this arrest of the circulation, but the high concentration of protein in the edema fluid indicated that increased permeability was also present.

Among the factors that might change capillary permeability under these conditions, the first to be considered are those associated with continued metabolism of tissues in the absence of blood flow, viz. a) reduced oxygen tension, b) increased carbon dioxide tension, and c) local decrease of pH due to accumulation of metabolites such as lactic acid. Table 6.4 summarizes the effects of these variables on the filtration coefficients (k_f) and on the in vivo effective osmotic pressures of the plasma proteins measured in single mesenteric capillaries of the frog (201). They indicate that Ringer's solution, saturated with CO_2 or acidified by HCl to pH's between 7.0 and 5.0, had no significant effect on the permeability of the capillary wall. Only when pH was made 4.0 or less, and hence unphysiologically low, was there evidence of increased permeability to fluid and protein.

Severe and, so far as possible, total oxygen lack made the capillary wall permeable to protein and fluid as indicated by decreased effective osmotic pressure of the plasma proteins and by increased filtration coefficient, respectively. It must be emphasized that the lowering of O_2 tension in these experiments was maximal because not only was blood flow stopped by tightening a loop around the mesenteric artery, but the mesentery was also irrigated freely with Ringer's solution previously boiled and kept saturated with nitrogen. The possibility that metabolites from anaerobic metabolism were responsible could not be excluded. The effects on permeability were, however, still reversible because, if the period of severe hypoxia was brief enough, e.g., 3 min, resumption of blood flow and irrigation with oxygenated Ringer's solution restored both the filtration coefficient and the in vivo osmotic pressure of the plasma proteins toward normal, as shown in table 6.4. For comparison, at the bottom of table 6.4

TABLE 6.4. *Effects of CO₂, O₂, pH, and Severe Chemical Injury on Frog's Mesenteric Capillaries*

| Capillaries Irrigated by Ringer's Fluid with | Filtration Coefficient, k_f $\frac{\mu^3}{\text{sec} \times \mu^2 \times \text{cm H}_2\text{O}}$ | Effective Π_{pl} (in vivo) cm H ₂ O |
|-------------------------------------------------------|----------------------------------------------------------------------------------------------------------|----------------------------------------------------------|
| Usual aeration | .0048-.0074* | 8.6-11.7* |
| Saturated CO ₂ | .0088 | 11.8 |
| pH 8.0 | .0056 | 11.5 |
| HCl to pH 6.0 | .0065 | 11.7 |
| 5.0 | .0074 | 11.4 |

is shown the still greater effect of chemical injury severe enough to produce irreversible capillary stasis.

In contrast to the effects of extreme local hypoxia just described, studies of graded hypoxemia have demonstrated that the capillary wall tolerates less severe grades of oxygen lack very well. In the human forearm, Henry *et al.* (150) found that oxygen tension of venous blood must be reduced to between 15 and 25 mm Hg before protein passage was increased above normal. This corresponds to an oxygen saturation of 15 to 25 per cent or an oxygen content of 4 to 6 vol per cent, assuming the blood has a normal hemoglobin content. The method used to measure protein passage was, however, indirect and the protein content of capillary filtrate varied widely.

DiPasquale & Schiller (70) and Hendley & Schiller (148) studied the effects of hypoxemia on the rate of edema formation in limbs of rats perfused with Krebs-Ringer solution containing 20 per cent washed red cells of dog and 0.33 per cent gelatin. When the oxygen content of the perfusing fluid was kept above 5 vol per cent, the rate of edema formation remained at the control level. Reducing oxygen content to between 0.88 and 2.60 vol per cent increased the rate of edema formation above control levels by 42 per cent in the first 20 min, by 87 per cent in the next 20 min, and by 151 per cent in the third 20-min period. Blood flow having been kept constant to exclude effects of the vasodilatation which accompanied this hypoxemia, they concluded that the critical level below which hypoxemia influences

the permeability of a capillary wall was probably about 2.6 vol per cent. No observations on protein passage were made. In further studies Hendley & Schiller (149) found, however, that either histaminic (Neo-Antergan) or adrenergic (Dibenzyliline) blockade eliminated these results on the basis either of specific blocking action or of hemodynamic effects, and the meaning of these studies therefore remains a challenging problem.

Systemic hypoxemia, within the range compatible with the life of the organism, has no certain effect on capillary permeability. Maurer (228, 229) and Warren & Drinker (367) found, in dogs, that breathing 8.0 to 11.5 per cent oxygen in nitrogen augmented the flow of lymph from the lungs and cervical region, increased the total amount of lymph protein collected in unit time, but decreased the concentration of protein in that lymph. Although an increase of capillary permeability was postulated, the decreased protein concentration in lymph, taken together with the studies of Courtice & Korner (53, 179) make it unlikely that permeability to protein was changed. In the human forearm McMichael & Morris (242) found that breathing 9.5 per cent oxygen did not increase filtration from capillaries during venous congestion. Moreover, in patients with generalized hypoxemia sufficient to impair cerebral function, Stead & Warren (351) observed no significant increase in the protein content of edema fluids collected from the extremities.

Only in agonal or antemortem stages of asphyxia (34) or anoxemia (160) is there some slight evidence of increased capillary permeability. In shock the possibility that generalized hypoxemia might increase capillary permeability has been considered on many occasions. Careful studies with labeled plasma proteins (45, 101, 102) have shown the expected rapid passage of protein through capillary walls locally in burned or crushed tissues. However, no abnormal passage through capillary walls elsewhere in the body has been found until just before death, again as an agonal or antemortem occurrence.

In view of the many uncertainties already mentioned it is important to note that Bayliss & Lunds-gaard (11) perfused isolated kidneys with cyanide-containing blood and found that some tubular functions were reduced conspicuously, but that the glomerular capillaries and membranes remained nevertheless normally impermeable to protein in the two instances tested. In an earlier study Starling & Verney (348) found that the urine contained only a trace of protein after 15 min of cyanide perfusion,

though stepwise increases of proteinuria occurred after that. Pappenheimer found (unpublished studies) in the perfused cat's leg by the isogravimetric method that cyanide did not, under certain conditions, increase either the filtration coefficient or the permeability of the capillary wall to protein. This raises the interesting possibility that any effects which severe hypoxia may have on capillary permeability do not involve the better known cyanide-sensitive oxidations, but involve rather the 2 to 50 per cent (71, 224) of tissue oxygen consumption which cyanide does not inhibit even in high concentration. It is possible, too, that the edema of prolonged ischemia arises from the effects of anaerobically produced metabolic products or from other substances liberated by hypoxic tissue cells. In summary, the effects on capillary permeability of arrested blood flow, and more specifically of hypoxia, are still uncertain and require more careful studies both as to quantitative aspects and as to mechanism.

ADRENAL CORTICAL HORMONES AND FILTRATION COEFFICIENTS. Adrenal hormones have frequently been considered to be a factor in maintaining filtration coefficients and capillary permeability within normal limits even after injury. Menkin (245) and others (110, 332) observed that adrenal extracts and some adrenal steroids inhibited or delayed the appearance of intravenously administered trypan blue in the skin of rabbits where leukotaxine (110, 245) or peptone (332) had been injected locally. Some blanching of the skin was observed in the area treated with adrenal cortical hormones (110, 332), suggesting possible vasoconstriction. Hyman & Chambers (163) found in the perfused hind legs of frogs that the rate of edema formation was reduced by addition of certain adrenal cortical extracts to the perfusing fluid, but their method, like the preceding ones, did not exclude possible changes in capillary blood pressure.

Renkin & Zaun (302) applied to this problem the isogravimetric perfusion method of Pappenheimer & Soto-Rivera (282) which permitted measurement of *a*) filtration coefficients to indicate permeability to fluid and protein, *b*) osmotic transients to indicate permeability to small molecules, and *c*) blood flow to identify vasoconstriction. Addition of adrenal cortical extracts to both normal and adrenalectomized preparations produced vasoconstriction which was shown to be due to the presence of small amounts of an easily oxidizable substance, presumably epinephrine. Limbs from adrenalectomized animals

showed no increase of capillary permeability to protein and filtration coefficients for fluid did not differ significantly from normal. Addition of adrenal cortical extracts to the perfusing fluid produced slight decreases of the filtration coefficient, but evidence of vasoconstriction was also present. The addition of epinephrine to the perfusing fluid in amounts similar to that contaminating the extract produced corresponding changes, both of resistance to flow and of filtration coefficient. Permeability of the capillary wall to sucrose was also normal in adrenalectomized rats and was not affected by aqueous adrenal cortical extract.

The lack of agreement concerning the effects of adrenal extracts and steroids emphasizes again (208) the necessity for devising methods which separate a direct action of substances on capillary permeability per se from the indirect effects of complicating vasodilatation or vasoconstriction. Vasodilatation can increase capillary blood pressure; thus favoring greater filtration through an unchanged capillary wall. Conversely, vasoconstriction can reduce capillary blood flow and pressure, and also the area of capillary wall available for diffusion and filtration. Such hemodynamic changes will, of themselves, modify exchanges of substances, and thus simulate a change of permeability. The quantitative measurement of increases or decreases of capillary permeability is still one of the most difficult problems in physiology.

POROSITY OF THE INJURED CAPILLARY WALL. The effect of injury on the size of possible pores in the capillary wall was considered by Krogh (184) in 1922. From the passage of soluble starch and the retention of carbon particles he concluded that pore diameter was not less than 50 Å nor more than 2000 Å. For normal limb capillaries of cats the present corrected estimate for mean effective pore diameter lies between 80 and 90 Å (see sections 8 to 10). If it be assumed *a*) that injury merely enlarges existing pores, and *b*) that Poiseuille's equation holds for filtration through these pores, then a sevenfold increase of filtration coefficient can be explained by a 65 per cent increase of pore diameter, i.e., from the normal 80 to 90 Å up to between 130 and 150 Å. Judging from the effects of reduced pH shown in table 6.4 a doubling of filtration coefficient does not increase protein passage measurably, whereas a threefold to fourfold increase does. It may be, however, that injury increases the size or number of the larger openings postulated by Grotte (126) and by

Mayerson *et al.* (232) or that ultramicroscopic disruption of vessel architecture produces new and still larger apertures. Electron microscopy has shown recently, for instance, that histamine can produce separation of endothelial cells in venules so that carbon particles pass between endothelial cells to rest against the basement membrane (226, 226a). Additional evidence in favor of enlarged leaks or of new openings in injury has been provided recently by Courtice & Morris (50-52, 54). Concentrations of total cholesterol and of phospholipids were studied in order to determine the plasma to lymph gradients of lipoproteins in the limbs of cats and rabbits before and after injury. These gradients were compared with those for albumin and globulins. In lymph from normal legs the concentrations of albumin, globulins, cholesterol, and phospholipids were, respectively, 48, 35, 24, and 33 per cent of the plasma levels. After thermal injury the corresponding figures for lymph were 81, 74, 60, and 74 per cent of the plasma levels. Increased permeability to protein was accompanied by increased permeability to lipoproteins, the diameters of which have been placed tentatively at 150 to 350 Å (144). Larger fat particles, measuring perhaps 1500 Å or more, e.g., the particles in chyle or in an artificial fat emulsion, were not transferred through the capillary wall to lymph to any measurable extent, even after injury. However, as Courtice mentions (52), although the passage of lipoproteins and lipids becomes less as the size of the molecule or complex increases, the exact mechanism of their passage, whether between or through endothelial cells, is still obscure. In addition, the molecular mechanism and ultramicroscopic location of capillary damage may well differ, depending upon the type of injurious agent involved (208). Hence the basic nature of Cohnheim's "molecular alteration in the vessel walls" in various types of injury remains still a prime unknown requiring study by pathologists, physiologists, and electron microscopists alike.

7. DIFFUSION, GENERAL PRINCIPLES

The extravascular circulation caused by capillary filtration and absorption is exceedingly important for homeostasis of blood volume and for removal of large protein molecules via the lymphatics. However, the magnitude of the extravascular circulation is too small to be of significance for the metabolic exchange of small molecules between blood and tissues (see fig. 5.2). Metabolic exchange takes place largely by diffusion processes which are almost independent of the magnitude and direction of net fluid movement.

Evidence to be discussed below indicates that diffusion of lipid-insoluble molecules takes place through aqueous channels between capillary endothelial cells. Lipid-soluble molecules, on the other hand, diffuse rapidly through the lipid plasma membranes of the endothelial cells themselves and are thus free to utilize the entire capillary surface area for the exchange process. Before undertaking a detailed analysis of diffusion processes in the capillary circulation, it will be helpful to review some physical laws governing molecular diffusion in free solution and in simple membranes.

A. Free Diffusion

The fundamental laws of free diffusion were first described by Fick (96) in 1855.

Adolf Fick (1829-1901) was Professor of Physiology in Würzburg. His most numerous publications were in the field of muscle physiology, but his several classical contributions to science were in the form of short, single publications in unrelated fields. Among circulatory physiologists he is known chiefly as the originator of the "Fick principle" for determination of cardiac output. Among ophthalmologists he is noted for the development of tonometry and as author of "Fick's law" relating deformation of the cornea to intraocular pressure. It is probable, however, that his greatest contribution to science was his clear formulation of the laws of diffusion based on analogy with Fourier's description of the flow of heat. "Die Verbreitung eines gelösten Körpers in Lösungsmittel geht, sofern sie ungestört unter dem ausschliesslichen Einfluss der Molecularkräfte stattfindet, nach demselben Gesetze vor sich, welches Fourier für die Verbreitung der Wärme in einem Leiter aufgestellt hat. . . Man darf nur in dem Fourier'schen Gesetz das Wort Wärmemenge mit dem Worte Quantität des gelösten Körpers, und das Wort Temperatur mit Lösungsdichtigkeit vertauschen."

According to Fick's formulation, the rate of linear diffusion (quantity, n , per unit time, t) in direction x and through cross-sectional area, A , is proportional to the concentration gradient, dc/dx .

$$dn/dt = D A dc/dx \quad (7.1)$$

The constant of proportionality, D , is known as the diffusion coefficient and its dimensions are l^2t^{-1} . The simplest possible application of equation 7.1 is to steady-state diffusion where dc/dt is constant as a function of both distance and time. In this case, the equation 7.1 can be written

$$\dot{n} = D A \Delta c / \Delta x \quad (7.2)$$

where the concentration gradient $\Delta c / \Delta x$ is constant all along the diffusion path. Equation 7.2 is specially applicable to diffusion through thin membranes where the concentrations on the two sides of the

membrane can be maintained constant. This condition is frequently encountered in the capillary circulation where blood on the luminal side of the capillary membrane is maintained at constant composition by virtue of an adequate blood flow and fluid on the tissue side of the capillary membrane is maintained at a different constant composition as a result of tissue metabolism. A specific example will serve to illustrate the use of equation 7.2 and at the same time indicate the magnitude of diffusion in systems of capillary dimensions. Consider the diffusion of glucose across an aqueous boundary .5 μ (0.5×10^{-4} cm) thick and with a surface area of 10 cm². The diffusion coefficient of glucose is 0.9×10^{-5} cm² per sec (see table 9.1). Let the concentration of glucose on one side of the boundary be maintained constant at 100 mg per cent and the concentration on the other side of the boundary at 99 mg per cent, thus producing a constant concentration difference of 0.01 mg per cm³. Substituting these values in equation 7.2, we have

$$\begin{aligned} \dot{n} &= .9 \times 10^{-5} \frac{\text{cm}^2}{\text{sec}} \times 10 \text{ cm}^2 \times \frac{.01 \text{ mg/cm}^3}{0.5 \times 10^{-4} \text{ cm}} \\ &= 0.018 \text{ mg/sec or } 1.08 \text{ mg/min} \end{aligned}$$

This rate of transfer is greater than the normal metabolic consumption of glucose in 100 g of skeletal muscle containing more than 5,000 cm² of total capillary surface and it is thus obvious that even a small concentration difference operating over a relatively small aqueous area will provide a physiologically sufficient diffusion flow of glucose through distances comparable in thickness with the capillary wall.

Fick realized that the driving force for diffusion results from random kinetic motions of the diffusing molecules, but he did not perceive the physical significance of the diffusion coefficient. It remained for Nernst (1888) to relate diffusion coefficient to osmotic and frictional forces in solution (260). Nernst showed that

$$D = RT/fN \quad (7.3)$$

where f is the frictional force opposing unit linear velocity of each molecule and N is the number of molecules per mole (Avogadro's number). For the case of large spherical molecules the frictional force opposing diffusion is given by Stokes' law describing the motion of a sphere falling at unit velocity in a viscous medium

$$f = 6\pi\eta a \quad (7.4)$$

where η is the viscosity of the medium and a is the molecular radius. In 1905 Sutherland (355) and Einstein (91) independently noted the possibility of combining equations 7.3 and 7.4 to obtain the relationship between free diffusion coefficient and molecular radius

$$D = RT/6\pi\eta a N \quad (7.5)$$

Equation 7.5 indicates that diffusion coefficient is inversely related to molecular radius and to the viscosity of the diffusion medium; conversely the equation allows calculation of molecular radius from measurements of free diffusion coefficient. It should perhaps be emphasized that molecules are rarely spherical and the molecular radius calculated from the Einstein-Stokes relation (equation 7.5) is a virtual quantity represented by a sphere of equivalent diffusion coefficient. Moreover, the equation is derived on the assumption that the diffusing molecules are large compared to the solvent molecules; for molecules smaller than glucose it is necessary to apply corrections such as those given by Gierer & Wirz (116). Additional methods for estimating molecular dimensions include calculations from density, intrinsic viscosity, and X-ray diffraction data. Table 9.1, based on more detailed tables published in references 82, 281, and 298, shows free diffusion coefficients and approximate molecular radii of a variety of molecular species which have been used in studies of capillary permeability.

B. Diffusion Through Porous Membranes, Restricted Diffusion

The diffusion of small molecules through thin, large-pored membranes takes place according to Fick's law; the only effect of the membrane is to reduce the total area available for free diffusion. Indeed, the most accurate method of estimating the pore area, A_p , in a membrane with large water-filled pores is to measure the diffusion rate, \dot{n} , through the membrane of small, uncharged molecules of known free diffusion coefficient. From rearrangement of Fick's law

$$A_p = \dot{n} \times \frac{\Delta x}{D\Delta c}$$

In most practical applications the path length, Δx , through the membrane is also unknown and it is more useful to solve for the pore area per unit path length, $A_p/\Delta x$

$$\frac{A_p}{\Delta x} = \frac{\dot{n}}{D \Delta c} \quad (7.6)$$

Once the pore area per unit path length, $A_p / \Delta x$, has been established from equation 7.6 for a given large-pored membrane, the membrane may be used to determine free diffusion coefficients of test molecules (233, 264, 316). Membranes employed for this purpose generally have pores which are at least 100-fold larger than the diffusing molecules.

In the case of diffusion through membranes having pores of molecular dimensions the kinetic motions of the diffusing molecules are restricted by the pore structure; in such membranes the effective pore area per unit path length decreases as a function of molecular size, becoming zero when the test molecules are the same size as the pores. Capillary permeability to lipid-insoluble molecules of graded sizes can be explained, in large part, by restricted diffusion through aqueous channels of molecular dimension. For this reason it will be necessary to discuss physical aspects of restricted diffusion in some detail.

Figure 7.1 shows apparent pore areas per unit path length for molecules of graded sizes diffusing through a cellulose membrane of the type commonly used for ultrafiltration or dialysis (Visking sausage casing). It is evident that the apparent pore area for free diffusion decreases rapidly as a function of molecular size. The true pore area in the membrane is, of course, constant and it is useful to think of the apparent decrease in terms of a restricted diffusion coefficient, D' , such that

$$D' = D A_s / A_p \quad (7.7)$$

where A_s is the apparent pore area for the solute and A_p is the true pore area. Substitution of D' for D in equation 7.6 would yield the true membrane pore area per unit path length for all molecular species. The essential theoretical problem is now to relate the observed restriction to diffusion, D'/D , to dimensions of the membrane pores.

The theory of restricted diffusion proposed by Pappenheimer *et al.* (281) takes into account two factors impeding the passage of molecules through pores of molecular dimensions. The first factor is concerned with steric hindrance at the entrance of the pore. It is assumed that for entrance into a pore a molecule must pass through the opening without striking the edge as originally suggested by Ferry (95). For the case of cylindrical pores the effective target area, A_s , for the solute is then

$$A_s = A_p (1 - a/r)^2 \quad (7.7a)$$

FIG. 7.1. Apparent pore areas per unit path length as a function of molecular size. The smooth curve is constructed from the theory of restricted diffusion, equation 7.9, assuming a mean pore radius of 16 Å. Mean pore radius determined on the same membrane from combination of diffusion and filtration was 19 Å (equation 7.13). Similar data for diffusion of lipid insoluble molecules through the walls of muscle capillaries are shown in figure 9.2. [Adapted from Renkin (298).]

where A_p is the true geometrical area of the opening and a/r is the ratio of molecular radius to pore radius.

The second factor takes account of friction between a molecule moving within a pore and the stationary walls of the pore. This factor, first studied by Ladenburg (193), was employed by Friedman & Kraemer (112) to describe the diffusion of sugars through gelatin gels. The Ladenburg treatment of the problem is strictly applicable only to cases where $a/r < .1$ and it is preferable to use the more general formulation of Faxén (94)

$$\frac{f}{f_0} = 1 - 2.10 \left(\frac{a}{r}\right) + 2.09 \left(\frac{a}{r}\right)^3 - 0.95 \left(\frac{a}{r}\right)^5 \quad (7.8)$$

where f/f_0 is the frictional resistance to diffusion in the pore relative to that in free solution. Taking into account both steric hindrance (equation 7.7a) and wall effects (equation 7.8), the theoretical restriction to diffusion through cylindrical pores becomes

$$\frac{A_s}{A_p} = \frac{D'}{D} = \left(1 - \frac{a}{r}\right)^2 \left[1 - 2.10 \left(\frac{a}{r}\right) + 2.09 \left(\frac{a}{r}\right)^3 - 0.95 \left(\frac{a}{r}\right)^5\right] \quad (7.9)$$

The last term of the series is negligible when $a/r < 0.5$. During net flow through the membrane the

velocity of flow at the center of the pore is twice the average velocity and the effective target area presented by the pore to the incoming molecules is slightly increased (95). Under these conditions the restricted diffusion equation becomes

$$\left(\frac{A_s}{A_p}\right)_{flow} = \left[2\left(1 - \frac{a}{r}\right)^2 - \left(1 - \frac{a}{r}\right)^4\right] \left[1 - 2.10\left(\frac{a}{r}\right) + 2.09\left(\frac{a}{r}\right)^3 - 0.95\left(\frac{a}{r}\right)^5\right] \quad (7.10)$$

Figure 7.2 shows that equation 7.9 describes observed diffusion through artificial porous membranes with considerable accuracy. The data were obtained using seven molecular species and three membranes having porosities in the range of interest for capillary physiology. Analogous development of theory for restriction to diffusion through rectangular slits, rather than cylindrical pores, leads to a theoretical curve closely approximating that shown in figure 7.2 (281). However, electron micrographs indicate that true pore geometry of artificial membranes is closer to the cylindrical than to the rectangular model (27).

Study of figure 7.2 reveals that pores of sufficient size to allow the slow penetration of plasma proteins (i.e., 30–40 Å) will nevertheless impose differential restriction to diffusion of much smaller molecules. Thus diffusion of glucose ($a = 3.7$ Å) through pores of radius 40 Å will be slowed by 34 per cent, whereas diffusion of water through the same pores will be slowed by only 14 per cent. This differential restriction to diffusion of small solutes and water is the

essential factor underlying transcapillary fluid shifts caused by transient changes in the concentration of small molecules in either plasma or tissue fluids.

The theory of restricted diffusion provides a method for estimation of effective pore radius, both in artificial membranes and in living capillaries. Thus equation 7.9 contains only two unknowns, D' and r , and it is therefore possible to solve for r from observed diffusion rates of two molecular species of known free diffusion coefficients and molecular radii. Greater accuracy can be obtained from the best fit of equation 7.9 to results obtained from several molecular species as shown in figure 7.1. Pore dimensions calculated from the theory of restricted diffusion agree well with values obtained by independent methods (298).

C. Diffusion and Hydrodynamic Flow, Relation to Pore Dimensions

Hydrostatic or osmotic forces, acting across a porous membrane, cause net fluid movement in proportion to the difference between hydrostatic and effective osmotic pressure (equation 1.1). Two different mechanisms are involved, diffusion and hydrodynamic flow.

DIFFUSION. The effective concentration (thermodynamic activity) of water depends upon pressure, temperature, and solute concentration. An increase of pressure or temperature increases the kinetic energy of the water molecules and therefore increases the statistical probability of net movement toward a region of lower pressure or temperature. Conversely, the addition of solute molecules to water decreases the probability of net diffusion of water to a region of lower solute concentration. For an ideal semipermeable membrane Fick's law may be restated as follows to take account of these variables

$$\frac{dn_{H_2O}}{dt} = \frac{\dot{q}}{\bar{V}_{H_2O}} = D_{H_2O} \frac{A_p}{\Delta x} \left(\frac{\Delta P - \Delta \Pi}{RT} \right) \quad (7.11)$$

where \dot{q} is rate of net water flow (ml/sec) and \bar{V}_{H_2O} is the partial molal volume of water (18 cm³/mole). The term $(\Delta p - \Delta \Pi)/RT$ replaces the concentration term in Fick's law and represents the difference in activity of water molecules on the two sides of the membrane. Formal derivations of equation 7.11 may be found in references (38) or (170).

HYDRODYNAMIC FLOW. The minimum dissipation of energy for net water flow through a membrane

FIG. 7.2. Restricted diffusion through artificial porous membranes of various pore sizes. The smooth curve is drawn from the theory of restricted diffusion, equation 7.9. [Adapted from Renkin (298).]

containing N cylindrical pores of radius r will occur if the velocity profile assumes the parabolic distribution of Poiseuille's law.

$$\begin{aligned}\dot{Q} &= \frac{N\pi r^4}{8\eta \Delta x} (\Delta P - \Delta \Pi) \\ &= \frac{A_p}{\Delta x} \frac{r^2}{8\eta} (\Delta P - \Delta \Pi)\end{aligned}\quad (7.12)$$

Equation 7.12 implies that hydrodynamic streaming occurs even when the hydrostatic pressure difference across the membrane is zero, i.e., during flow caused by purely osmotic forces. The question is often raised as to how Poiseuille flow could occur in the apparent absence of a difference in hydrostatic pressure. An explanation of this apparent paradox was first offered in an important paper by Schlögl (317) who pointed out that a hydrostatic pressure drop accounting for hydrodynamic flow does indeed exist along most of the length of the membrane pores, even though the hydrostatic pressures on the two sides of the membrane are equal. The intra-membrane hydrostatic pressure gradient reverses sharply near the edge of the pore where it becomes equal and opposite to the steep gradient of diffusion potential. A more detailed treatment of this hypothesis will be found in the recent paper by Ray (292).

Comparison of equation 7.11 with equation 7.12 reveals that for a given total pore area, A_p , net flow by diffusion is independent of pore radius, whereas hydrodynamic flow varies with the second power of the pore radius. It follows that for a given difference in hydrostatic pressure the hydrodynamic component of flow will increase rapidly as a function of pore size. Figure 7.3 shows the relative importance of diffusion and hydrodynamic flow as a function of pore radius. For porosities in the range of interest for capillary permeability (e.g., 20–50 Å) the hydrodynamic component of net flow is overwhelmingly greater than the diffusion component. The capillary filtration coefficient discussed in section 6 is therefore a measure of hydrodynamic conductivity rather than diffusion permeability. Detailed discussions of the relations between diffusion permeability and hydrodynamic conductivity will be found in papers by Koefoed-Johnson & Ussing (177), Pappenheimer (276, 277), Garby (113), Durbin *et al.* (83) Kedem & Katchalsky (170) Katchalsky (169), Mauro (230), and Ray (292). A recent experimental evaluation of diffusion and hydrodynamic flow through artificial membranes has been published by Robbins & Mauro (303).

Combination of diffusion data with hydrodynamic

FIG. 7.3. Net diffusion and hydrodynamic flow of water as a function of pore size during flow induced by hydrostatic or osmotic forces. For membranes with effective pore radii greater than about 20 Å the net flow of water by diffusion is negligible compared to hydrodynamic flow. [From Pappenheimer (276).]

data leads to a solution for pore dimensions. Equation 7.11 describing hydrodynamic or osmotic flow through cylindrical pores can be rearranged to give

$$r = \sqrt{\frac{\dot{Q}_f}{(\Delta P - \Delta \Pi)} \times \frac{8\eta}{A_w/\Delta x}}$$

But $\dot{Q}/(\Delta P - \Delta \Pi)$ is the filtration coefficient defined by equation 1.1 and $(A_w/\Delta x)$ can be determined from diffusion of labeled water as shown in figure 7.1. Therefore, the effective pore radius is defined by measurable quantities

$$r = \sqrt{\frac{8\eta K_f}{A_w/\Delta x}} \quad (7.13)$$

Similar equations, based on diffusion and hydrodynamic flow, can be derived to estimate the dimensions of slit pores (18, 281) or any other pore geometry for which the laws of hydrodynamic flow are known.

Equation 7.13 has been used to estimate pore size in artificial membranes (82, 298) and in living capillaries (281). In general there is good agreement between pore size estimated from flow and diffusion and pore size estimated from restricted diffusion (fig. 7.1).

D. Simultaneous Flow and Restricted Diffusion: Theory of Molecular Sieving

In the capillary circulation both filtration and restricted diffusion usually occur simultaneously and

these two processes, operating together, are largely responsible for observed concentrations of large molecules in lymph (126) and renal glomerular filtrate (194, 278, 366). From the theory of molecular sieving described below it is possible to make deductions concerning capillary permeability for comparison with results obtained by independent methods. The degree of molecular sieving of a given solute may be defined as the ratio of its concentration in the filtrate (c_2) to its concentration in the filtrand (c_1). It is often supposed that during ultrafiltration of a monodisperse solute through an isoporous membrane, the value of c_2/c_1 will be zero when the pores are smaller than the solute molecules and unity when the pores are larger than the solute molecules. If intermediate values are actually observed they are said to be evidence for heteroporosity. If, for example, the concentration of a given solute in a capillary ultrafiltrate is 50 per cent of that in plasma it is supposed that half the capillary pores were smaller than the solute molecules and half were larger (21, 208, 232, 254). This reasoning fails to explain the dependence of molecular sieving on filtration rate. The following considerations show that molecular sieving of a monodisperse solute through an isoporous membrane is determined by the ratio of restricted diffusion to rate of filtration.

If the passage of solute through a porous membrane is restricted relative to passage of solvent, then the

$$\frac{c_2}{c_1} = \frac{1 + \frac{D_s}{\dot{Q}_f} \times \frac{A_w}{\Delta x}}{\frac{\left[2\left(1 - \frac{a_w}{r}\right)^2 - \left(1 - \frac{a_w}{r}\right)^4\right] \left[1 - 2.10\left(\frac{a_w}{r}\right) + 2.09\left(\frac{a_w}{r}\right)^3 - 0.95\left(\frac{a_w}{r}\right)^5\right]}{\left[2\left(1 - \frac{a_s}{r}\right)^2 - \left(1 - \frac{a_s}{r}\right)^4\right] \left[1 - 2.10\left(\frac{a_s}{r}\right) + 2.09\left(\frac{a_s}{r}\right)^3 - 0.95\left(\frac{a_s}{r}\right)^5\right]} + \frac{D_s}{\dot{Q}_f} \times \frac{A_w}{\Delta x}} \quad (7.15)$$

filtrate will be diluted during filtration, thus giving rise to a concentration difference for diffusion at a rate determined by the restricted diffusion coefficient, D' , through the membrane. The ultimate steady-state composition of the filtrate relative to filtrand (c_2/c_1) is therefore determined by a race between hydrodynamic flow (\dot{Q}_f) tending to dilute the filtrate and restricted diffusion tending to restore the concentration difference. A quantitative expression for molecular sieving through isoporous membranes was derived by Pappenheimer (276)

$$\frac{c_2}{c_1} = \frac{1 + \frac{D_s}{\dot{Q}_f} \times \frac{A_w}{\Delta x}}{\frac{A_w}{A_s} + \frac{D_s}{\dot{Q}_f} \times \frac{A_w}{\Delta x}} \quad (7.14)$$

Inspection of equation 7.14 shows that at low rates of

filtration, c_2 approaches c_1 (dialysis) and at high rates of filtration c_2/c_1 approaches the ratio of restricted pore areas A_s/A_w . Equation 7.14 is derived on the assumption that the concentration gradient through the membrane is linear. Grotte (126), Garby (113), and Kuhn (192) have pointed out that the concentration gradient in the membrane will in general be an exponential function of flow velocity, but this correction was shown by Grotte to be a small one and will be neglected here.

The restricted pore areas, A_w and A_s , have been expressed by equation 7.10 as a function of molecular radius and pore radius. Substitution of this function in equation 7.14 yields a cumbersome but explicit expression for molecular sieving as a function of filtration rate when molecular and membrane pore dimensions are known; conversely, it provides an independent method for calculation of pore size from experimental measurements of molecular sieving and filtration rate.

Figure 7.4 shows experimentally determined values of molecular sieving as a function of filtration rate through Visking dialysis membrane. The theoretical curves were drawn according to equation 7.15, using the value of $A_w/\Delta x$ determined from diffusion of tritiated water and choosing pore radii to provide the best fits to the experimental data for each molecular species. Satisfactory fits were obtained with pore radii 15 to 17 Å. Pore radius for the same membrane estimated from the theory of restricted diffusion

(fig. 7.1) was 16 Å, and pore radius estimated from combination with Poiseuille's law was 19 Å (equation 7.13). The internal consistency of these various estimates of pore radius in artificial membranes constitutes the chief evidence justifying the application of similar techniques to biological membranes.

E. Distribution of Pore Sizes

Observed values for diffusion and molecular sieving through artificial porous membranes are in reasonable accord with theoretical predictions for isoporous membranes. Equal or slightly better agreement between experiment and theory can be obtained by assuming certain limited distributions of pore sizes (298). An upper limit to pore size may be determined

FIG. 7.4. Molecular sieving through an artificial, porous membrane. The smooth curves are constructed from the theory of molecular sieving, equation 7.15. The data fit pore radii in the range 15–17 Å. Mean pore radius for the same membrane estimated from the theory of restricted diffusion was 16 Å and pore radius estimated from combination with Poiseuille's law was 19 Å. The internal consistency of these various estimates of pore radius in artificial membranes constitutes the chief evidence justifying the application of similar techniques to biological membranes of comparable pore size. [Adapted from Renkin (298).]

from the size of the largest molecule which just fails to pass through the membrane. A less obvious limit to any assumed distribution arises from the fact that filtration rate varies with the fourth power of the radius so that the total fraction of large pores must be limited in order to satisfy the requirements imposed by the observed filtration coefficient. If a membrane contains cylindrical pores of different radii then the mean equivalent pore radius, \bar{r} , for hydrodynamic flow is given by

$$\bar{r} = \sqrt[4]{F_1 r_1^4 + F_2 r_2^4 + \cdots + F_n r_n^4} \quad (7.16)$$

where F_n is the fraction of total pore population having a radius r_n . For example, the membrane illustrated in figures 7.1 and 7.4 did not allow the passage of hemoglobin (a 32 Å) and therefore an upper limit to its pore size distribution is 32 Å. However, less than 20 per cent of the pores could be as large as 30 Å otherwise

$$\bar{r} > \sqrt[4]{0.2 \times (30)^4} > 20 \text{ Å}$$

which would not fit the requirement that $r = 19$ Å set by the observed filtration coefficient and diffusion

area for water (equation 7.13). The detailed computation of possible pore distributions which would fit the data for filtration, restricted diffusion and molecular sieving is possible but laborious. For the membrane illustrated in figures 7.1 and 7.4 the broadest Gaussian distribution of pore radii compatible with the data is defined by a mean pore radius of 14 Å with a standard deviation of 7 Å (298).

F. Osmotic Pressure³ and Osmotic Flow Through Leaky Membranes; Osmotic Reflection Coefficients

Van't Hoff's law relating osmotic pressure to concentration was derived for a perfectly semi-permeable membrane. Relatively little is known of osmotic forces associated with diffusion and osmotic flow through membranes which restrict, but do not prevent entirely, the diffusion of solute molecules. The quantitative significance of this problem may be illustrated by a specific example. Consider a two-compartment system separated by a membrane containing pores of radius 30 Å. Addition to one compartment of an ideal solute of molecular radius 30 Å will cause osmotic flow through the membrane at a rate equal to that caused by a hydrostatic pressure difference of cRT mm Hg (equation 7.12). However, if the same molar concentration of a small molecule such as urea (molecular radius 2.7 Å) is added to one compartment, it will be found that the osmotic flow is less than 5 per cent of that obtained by the hydrostatic equivalent (82).

In 1951 Staverman (349, 350) introduced the expression "osmotic reflection coefficient," σ , as an empirical descriptive term modifying van't Hoff's law for the case of leaky membranes.

$$\Pi = CRT\sigma \quad (7.17)$$

The value of σ ranges from unity in perfectly semi-permeable membranes to less than zero when the mobility of the solute exceeds that of the solvent (333).

Very small values of σ have been reported for osmotic flow caused by small molecules diffusing

³ "Osmotic pressure" is ordinarily defined for the case of thermodynamic equilibrium across ideal semipermeable membranes and the term has no equivalent meaning for the irreversible process to be considered here. Possibly a different term should be coined to describe the transmembrane pressures arising during restricted diffusion through porous membranes. "Restricted diffusion pressure" would be accurate but could only be applied to the case of zero net flow of solvent through the membrane.

through large pored artificial membranes. Thus Meschia & Setnikar (250) found that less than 2 per cent of the ideal osmotic potential was developed by sucrose during osmotic flow through a collodion membrane having pores of radius 110 Å (i.e., when the radius of the pore was approximately 25-fold greater than the radius of the diffusing molecule). Similarly low values for osmotic reflection coefficient have been reported by Grim (125) and by Shuler *et al.* (333) on the basis of osmotic flow through uncalibrated membranes.

Durbin (82) has recently completed a study of osmotic flow caused by molecules of graded sizes diffusing through calibrated porous membranes. His results shows that

$$\sigma \leq \left(1 - \frac{A_s}{A_w}\right)$$

where A_s is the restricted pore area available to the solute and A_w is the restricted pore area available to the solvent as defined by equation 7.9 and figure 7.1. Durbin's results indicate that during osmotic flow through artificial membranes the value of σ is less than 0.1 when the radius of the diffusing molecule is 10 per cent of the radius of the pore.

From existing data one must therefore conclude that only a small fraction of the theoretical van't Hoff pressure is operative across artificial membranes during restricted diffusion of small molecules through the membranes. On the other hand, relatively large osmotic forces have been observed during the restricted diffusion of small molecules through biological membranes under conditions involving little or no net fluid movement (122, 281). Under these conditions the osmotic reflection coefficient appears to depend upon the restricted diffusion coefficient of solute relative to that of the solvent.

$$\sigma = \left(1 - \frac{D'_s}{D'_w}\right) = \left(1 - \frac{A_s}{A_w} \times \frac{D_s}{D_w}\right) \quad (7.18)$$

Combination of equation 7.18 with equation 7.9 allows numerical evaluation of σ for the case of zero net fluid movement when molecular radius and pore radius are known. Thus,

$$\sigma_s = 1 - \frac{D_s}{D_w} \left\{ \frac{\left(1 - \frac{a_s}{r}\right)^2 \left[1 - 2.10\left(\frac{a_s}{r}\right) + 2.09\left(\frac{a_s}{r}\right)^3 - 0.95\left(\frac{a_s}{r}\right)^5\right]}{\left(1 - \frac{a_w}{r}\right)^2 \left[1 - 2.10\left(\frac{a_w}{r}\right) + 2.09\left(\frac{a_w}{r}\right)^3 - 0.95\left(\frac{a_w}{r}\right)^5\right]} \right\} \quad (7.19)$$

Equation 7.19 is specially applicable to capillary membranes where osmotic forces can be measured

rapidly in the virtual absence of net fluid movement (281).

In experiments involving artificial membranes it is exceedingly difficult to measure osmotic forces in the absence of osmotic flow, as pointed out in section 3. For this reason all investigations of osmotic reflection coefficient in artificial systems have thus far involved net flow of fluid. Under these conditions the frictional forces determining osmotic reflection coefficient will contain hydrodynamic as well as diffusional terms as emphasized in recent derivations by Ray (292) and Katchalsky (169). Discussion of these derivations is beyond the scope of this chapter but it seems fair to say that no well-substantiated theory is yet available to predict osmotic reflection coefficients as a function of membrane permeability and flow rate. Since most biological membranes allow the restricted passage of environmental solutes, the problem remains as one of the most important unsolved questions in contemporary studies of permeability.

8. TRANSCAPILLARY MOVEMENT OF LIPID-INSOLUBLE MOLECULES

The concentration gradients which provide the driving force for diffusion exchange between blood and tissues are normally maintained by tissue metabolism. However, the transcapillary exchange process is so efficient that normal transcapillary concentration differences of small molecules would be too small to be detectable by existing methods, even supposing it were feasible to collect, for analysis, tissue fluid from the immediate vicinity of the capillary wall. From an experimental point of view it is therefore necessary to establish abnormally large transcapillary concentration ratios in order to study diffusion characteristics of the capillary walls.

Figure 8.1 summarizes data showing rates of disappearance from the circulatory system of various lipid-insoluble substances which distribute primarily in extracellular fluid. It is evident that these substances leave the vascular system at rates which vary

inversely with molecular size. Disappearance from plasma is accompanied by simultaneous appearance

FIG. 8.1. Disappearance of substances from arterial plasma of rabbits. Data for albumin are from Gitlin *et al.* (118), data for inulin and sucrose are from Kruhoffer (190, 191), and data for NaCl are from Morel (257). C is concentration in arterial plasma at time t ; C_{eq} is concentration in plasma at equilibrium; C_0 is initial concentration in arterial plasma obtained by extrapolation to zero time.

of the test molecules in tissue spaces, again at rates which vary inversely with molecular size. Most tissues of the body participate in the distribution process, though at widely different rates.

The rapid penetration of capillary walls by molecules as large as sucrose or inulin implies a high order of permeability to lipid-insoluble molecules. Cell membranes generally (i.e., the plasma membranes which envelop the protoplasm of all living cells) are virtually impermeable to metabolically inert, lipid-insoluble molecules as large as sucrose; indeed they generally have a low order of permeability to most ions. The behavior illustrated in figure 8.1 is more characteristic of artificial porous membranes and this resemblance has given rise to the hypothesis that capillary blood communicates directly with extravascular fluid via a system of aqueous pores or channels. Recent studies of capillary ultrastructure (93) support earlier views (37, 276) that the structural basis for this type of permeability is associated with junctional regions between capillary endothelial cells. The number, dimensions, and properties of transcapillary pores which would be necessary to account

for observed capillary permeability to lipid-insoluble molecules will be considered more fully in section 9.

Initial experiments with isotopic tracers led to the suggestion that arterial disappearance curves might provide a quantitative measure of capillary permeability (106, 138). For this purpose it was assumed that diffusion from blood to extravascular space could be represented by a simple two-compartment diffusion system separated by the capillary membranes and that concentrations in each compartment would be uniform at each moment during the diffusion process. The theoretical equation describing diffusion in this simplified model is easily derived from Fick's law and leads to the expression

$$\lambda = - \frac{DA_s}{\Delta x} \frac{(V_1 + V_2)}{V_1 V_2} \quad (8.1)$$

where λ is the (negative) slope of the observed exponential disappearance curve, V_1 is plasma volume and V_2 is extravascular distribution volume (106, 233). Reference to equation 7.2 shows that the term $DA_s / \Delta x$ is the flux per unit concentration difference, $\dot{n} / \Delta c$, and is therefore a direct measure of capillary permeability to the test molecules. More complex equations describing arterial disappearance curves have been derived to take account of loss by the kidneys, loss by metabolism and distribution between more than two compartments in series or in parallel (318, 319, 330, 341, 363).

Equation 8.1 is specially applicable to the case of large, lipid-insoluble molecules such as proteins or synthetic polymers. Diffusion of such substances from the vascular system is so slow that their concentrations in arterial plasma may be taken as a close approximation of mean concentration in capillary plasma, i.e., the concentration gradient along the length of each capillary is negligible at all times during the diffusion process. In the example of figure 8.1 the slope, λ , for albumin is about -0.1 per cent of the initial concentration per min, or 100 per cent of the plasma albumin every 16.6 hours. Similar values for transcapillary exchange rates of serum albumin have been observed in dog (370) and man (352). The free diffusion coefficient of albumin is 0.085×10^{-5} cm² per sec. Given a normal plasma volume, V_1 , of 4 per cent of body weight and a normal extracellular fluid volume, V_2 , of 20 per cent then from equation 8.1 the effective capillary pore area per unit path length available for restricted diffusion of serum albumin is 65 cm per 100 g tissue. This value may be compared with the value of 70 cm per 100 g muscle calculated

from the theory of restricted diffusion through pores of radius 43 Å (table 9.1).

Arterial disappearance curves therefore provide a method for quantitative studies of overall capillary permeability to large molecules. It is not possible, however, to extend this type of analysis to molecules which diffuse rapidly through capillary walls. In this case the mean concentration in capillary plasma may be only a small fraction of that in arterial plasma, particularly in early phases of the distribution process. Application of equation 8.1 to such data leads to estimates of capillary permeability which are too low, often by 1 or 2 orders of magnitude [see (281) and (382) for critical review]. Factors which determine mean concentration differences of small molecules across capillary walls during diffusion include rate of blood flow, diffusion rate, and the geometry and volume of extravascular diffusion space. Several interesting attempts have been made to take account of these factors by mathematical techniques but the solutions are complex and involve assumptions which are difficult to evaluate experimentally (19, 319).

Specialized experimental methods for estimating capillary permeability to small molecules were developed by Pappenheimer *et al.* (281) for the study of molecular exchanges in the capillary circulation of hind limbs of cats or dogs. Results obtained by these methods lead to conclusions of general interest relating capillary permeability to the number and dimensions of capillary pores which would be required to explain observed transcapillary diffusion rates of lipid-insoluble molecules ranging in size from D₂O to hemoglobin.

9. STRUCTURE OF MUSCLE CAPILLARIES AS DEDUCED FROM PERMEABILITY MEASUREMENTS AND FROM ELECTRON MICROSCOPY. QUANTITATIVE ASPECTS OF TRANSCAPILLARY DIFFUSION

In isolated perfused tissues the rate of net transcapillary movement of test substances can be determined from the product of blood flow and arterio-venous concentration difference. Thus,

$$\dot{n} = Q(c_a - c_v) \quad (9.1)$$

where Q is blood (or plasma) flow and c_a , c_v are the simultaneously measured concentrations of the test substance in arterial and venous bloods (or plasma).

The driving force for diffusion (i.e., the mean concentration difference across the capillary walls) may be estimated from the partial osmotic pressure

FIG. 9.1. Diffusion of raffinose from the capillaries of a perfused cat hind limb. At zero time 20 mm/liter raffinose was added to the perfusion reservoir. The final distribution volume of raffinose in perfused tissue was 19% of limb volume. The capillary diffusion area per unit path length calculated for raffinose was 0.38×10^5 cm²; this value was independent of time, extravascular fluid volume, or of mechanically induced changes of blood flow. [Adapted from Pappenheimer *et al.* (281).]

exerted by the test molecules during the diffusion process. Figure 9.1 illustrates a typical experiment showing the simultaneous measurement of net flux rate and partial osmotic pressure during the diffusion of raffinose from the capillaries of a perfused cat hind limb. The ratio of flux rate to partial osmotic pressure is proportional to permeability and may be related to the restricted pore area per unit path length in the capillary wall by combining equations 7.6 and 7.17.

$$\frac{A_s}{\Delta x} = \frac{RT\sigma_s}{D_s} \times \frac{\dot{n}}{\Delta \Pi} \quad (9.2)$$

FIG. 9.2. Restricted diffusion of lipid-insoluble molecules from the capillaries of perfused cat hind limbs. Each point represents the mean value of data from several experiments. The curves are constructed from the theory of restricted diffusion and filtration (equation 9.3) on the assumption that the osmotic reflection coefficient is determined by equation 7.19. The data fit theoretical restricted diffusion through pores of radius 40–45 Å in a membrane having the same filtration coefficient as the capillaries in the hind limb. [Recalculated from the data of Pappenheimer *et al.* (281).]

The upper panel of figure 9.1 shows that for raffinose the restricted pore area per unit path

$$r^2 \left\{ \frac{\left(1 - \frac{a_w}{r}\right)^2 \left[1 - 2.10\left(\frac{a_w}{r}\right) + 2.09\left(\frac{a_w}{r}\right)^3 - 0.95\left(\frac{a_w}{r}\right)^5\right]}{\left(1 - \frac{a_s}{r}\right)^2 \left[1 - 2.10\left(\frac{a_s}{r}\right) + 2.09\left(\frac{a_s}{r}\right)^3 - 0.95\left(\frac{a_s}{r}\right)^5\right]} - \frac{D_s}{D_w} \right\} = \frac{8\eta K_f}{RTD_s} \times \frac{\Delta\pi}{\dot{n}} \quad (9.3)$$

length, calculated from equation 9.2, was $0.38 \pm .04 \times 10^5$ cm. Results of similar measurements, made with a variety of molecular species, are shown in figure 9.2. It is seen that in capillaries, as in artificial porous membranes (fig. 7.1), the restricted pore area decreased as a function of molecular radius as predicted from the theory of restricted diffusion (equation 7.9). Extrapolation to zero molecular radius suggests that the true pore area per unit path length in the capillaries of 100 g muscle is approximately 0.6×10^5 cm. Since the average thickness of the capillary walls is less than 10^{-4} cm (fig. 9.3), this suggests that the total pore area available for diffusion exchange of lipid-insoluble molecules is less than 6

cm² or less than 0.1 per cent of the total capillary surface area in 100 g muscle. This conclusion is consistent with the view that transepillary exchanges of lipid-insoluble molecules take place at junctional regions between endothelial cells and we have already seen that pore areas of this magnitude can provide a physiologically sufficient flow of small molecules under the influence of small concentration gradients (section 7 A).

In the original analysis of Pappenheimer *et al.* (281) the mean pore radius was estimated from combination of the capillary filtration coefficient with the pore area per unit path length for a molecule the size of water (equation 7.13). However, the latter quantity was uncorrected for the osmotic reflection coefficient and therefore cannot be employed for the present analysis in which the osmotic reflection coefficient is included as an unknown. In order to solve for this additional unknown it is necessary to introduce an additional equation relating osmotic reflection coefficient to pore dimensions as suggested by equation 7.19. This equation is cumbersome and its use may not be entirely justified on the basis of our present inadequate knowledge of factors determining osmotic reflection coefficients. Nevertheless, it leads to a solution for capillary pore dimensions which is more consistent with available data than the dimensions originally proposed by Pappenheimer *et al.* (281). Substitution of equations 7.19 and 9.2 in equation 7.13 yields

where

- r = mean capillary pore radius, Å
- a_w = radius of water molecule = 1.5 Å
- a_s = radius of test molecule, Å
- D_w = free diffusion coefficient of water = 3.4×10^{-5} cm² per sec⁻¹
- D_s = free diffusion coefficient of test molecule
- η = viscosity of water = 0.007 dyne-sec-cm⁻² at 37 C
- K_f = filtration coefficient of capillaries, average value 1.8×10^{-7} cm⁵-dyne⁻¹-sec⁻¹ per 100 g
- $\Delta\pi$ = observed partial osmotic pressure, dynes-cm⁻² at time, t
- \dot{n} = observed flux rate, mole-cm² at time, t
- RT = 25×10^9 dyne-cm-mol⁻¹ at 37 C

Study of equation 9.3 in relation to the experimental

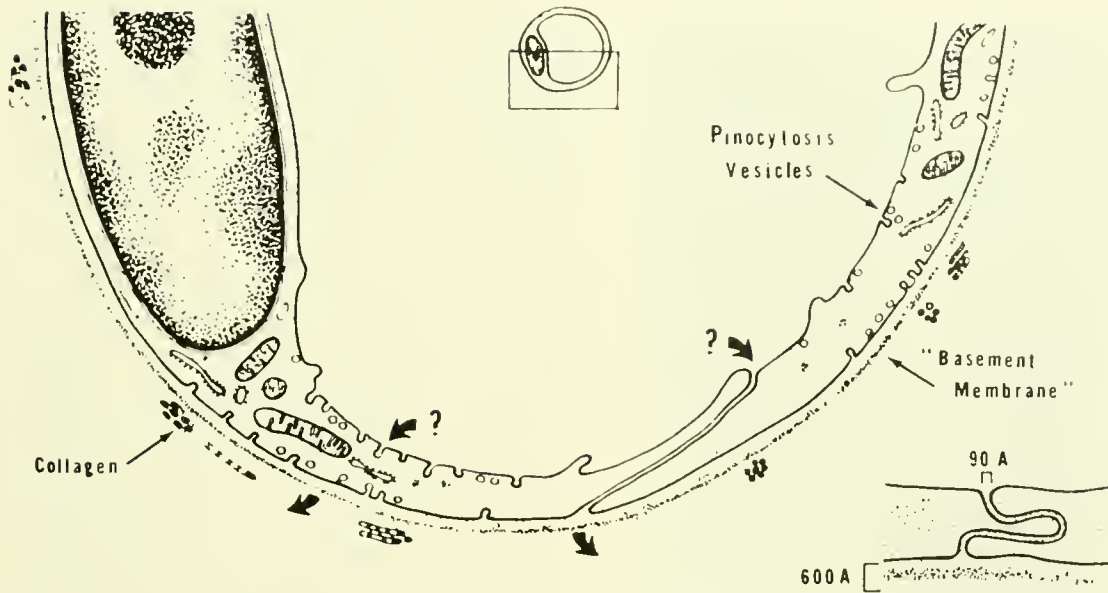

FIG. 9.3. Diagram illustrating current concepts of fine structure in muscle capillaries. [From Fawcett (93).] The nucleus of a single endothelial cell is shown at left. The capillary cross section may be formed by a single cell rolled into a tube or may be made up of several cells. The interendothelial region appears as a thin slit pore with direct connection from inside to outside of capillary. The slit may be straight or slightly tortuous (inset and fig. 9.4) and is usually about 90 Å wide and 0.5–1 μ in length. It occupies only a fraction of 1% of the total endothelial surface. The cytoplasm contains the usual organelles, but in addition contains numerous small vesicles and in-pocketings of the surface which are characteristic of microphagocytosis or pinocytosis. Palade (273) has suggested that this mechanism may be involved in the transcapillary passage of particles which are too large to traverse interendothelial openings. The outer surface of the endothelium is enveloped by an amorphous basement membrane about 600 Å in thickness and with histochemical properties indicative of a mucopolysaccharide. The permeability properties of this membrane are unknown. Dilute solutions of mucopolysaccharides, in contrast to gelatin-gels (112), may offer appreciable resistance to free diffusion (266). Finally, it should be emphasized that the diagram refers only to muscle capillaries. Morphological differences between capillaries in different vascular beds have been reviewed by Bennett *et al.* (13).

data of figure 9.2 reveals that the pore radius, r , is the only unknown quantity. The numerical evaluation of r from equation 9.3 may be carried out by successive approximation or by graphical analysis. For the specific example illustrated in figure 9.1 the value of r is 41 Å. Similar analysis of data for NaCl, urea, glucose, and sucrose leads to mean pore radii of 44, 43, 45, and 41 Å, respectively. These results are in accord with values in the range 35 to 45 Å estimated by Grotte (126) from molecular sieving of dextrans in hind limb capillaries (section 10 and fig. 10.1). They are in contrast to the value of 30 Å estimated by Pappenheimer *et al.* (281) from combination of filtration coefficient with uncorrected diffusion data and to the value of 25 Å estimated by Renkin & Pappenheimer (301) from uncorrected restriction to diffusion. The dimensions and fractional

surface area of aqueous transcapillary pores correspond closely with dimensions of interendothelial junctions as determined by electron microscopy. Figure 9.3 summarizes pertinent aspects of pore structure in muscle capillaries; details of a typical interendothelial junction are illustrated in figure 9.4. On the basis of present information we can compare the permeability of capillaries in 100 g of muscle to that of an artificial membrane, 7000 cm^2 in total area, 0.5 μ thick and containing 5×10^{12} uniform, water-filled, cylindrical pores of radius 40 to 45 Å. Such an artificial membrane would have the same filtration coefficient as the capillaries in 100 g muscle and would restrict the diffusion of uncharged, lipid-insoluble molecules to about the same degree (fig. 9.2). There are no reasons for supposing, however, that the channels through capillary walls are either

FIG. 9.4. A portion of the wall of a capillary (heart muscle) to show details of the interendothelial junction. The junction provides a continuous channel connecting the inside of the capillary with the outside basement membrane. The width of the channel is about 100 Å. The interior of the capillary is almost filled with an erythrocyte. [From Fawcett (93).]

cylindrical or perfectly uniform. Alternative models utilizing different pore geometries or a limited distribution of pore sizes could be devised to simulate observed capillary permeability. The significant fact is that both the hydrodynamic and diffusional characteristics of the capillaries can be explained in terms of a simple physical model which closely approximates the morphology of the capillary wall. The mean pore radius calculated as above may be regarded as analogous to the Einstein-Stokes molecular radius (equation 7.5) which by itself tells nothing of the actual shape of the molecule but is nevertheless valuable for predicting kinetic behavior.

The restricted pore areas shown in figure 9.2 represent only a minute fraction of the total capillary surface, but they nevertheless provide for extremely rapid transcapillary diffusion of small lipid-insoluble molecules. The pore area per unit path length avail-

able for diffusion of water through the capillary walls of 100 g muscle is about 0.6×10^5 cm (fig. 9.2). The concentration of water available for diffusion in either direction is about 55 molar (0.99 g/ml) and the diffusion coefficient of water is 3.4×10^5 cm² per sec. Substitution of these values in Fick's diffusion equation leads to a calculated diffusion rate of 2 g per sec. Since the total volume of plasma in the capillaries of 100 g of muscle is only about 1 ml, this suggests that plasma water exchanges 2 times per sec or 120 times per min with the interstitial water immediately surrounding the capillaries. Similar calculations for NaCl, urea, and glucose yield exchange rate of 60, 55, and 30 times the plasma content of these substances per minute. An alternative method of expressing the results is in terms of the ratio of exchange rate to plasma flow. The latter is generally in the range 2 to 4 ml per min per 100 g tissue. Taking 3 ml per min as an average, we would estimate that the diffusion of water, NaCl, urea, and glucose back and forth through the capillary wall occurs at rates which are, respectively, 40, 20, 18, and 10 times the rate at which these substances are brought to the tissues by the incoming blood. In contrast, the extravascular circulation of fluid caused by net filtration and absorption is only about 2 per cent of the plasma flow as indicated in figure 5.2. For this reason the rates of exchange of small molecules between blood and tissues are but little affected by simultaneous net fluid movement. For example, *p*-aminohippurate and related substances diffuse rapidly out of the peritubular capillaries in the direction opposite to net fluid flow (peritubular capillary reabsorption). The rates of clearance of Na²⁴ or I¹³¹ from skin are not appreciably affected by concurrent edema formation (164).

The permeability of biological membranes is usually expressed in terms of flux rate per unit concentration difference divided by the area, A_m , of the entire membrane surface (specific permeability coefficient)

$$P_s = \frac{\dot{n}}{\Delta c} \div A_m = \frac{D_s A_s}{A_m \Delta x} \quad (9.4)$$

Values of P_s for muscle capillaries are listed in table 9.1. Information of the type summarized in table 9.1 is not yet available from capillaries in regions other than muscle, with the possible exception of renal glomerular capillaries (section 10). Nevertheless, there are many indications that permeability properties of capillaries may differ greatly in different organs. Studies of the rates at which labeled proteins or dextran fractions appear in lymph from different regions suggest that porosity of capillaries in visceral organs may be considerably greater than in capillaries

* From smooth curves of figure 9.2. † Mols/sec/cm² membrane per mol/ml concentration difference. The total membrane surface in 100 g muscle, A_m , is assumed to be 7000 cm² (281). ‡ Calculated from over all bodily arterial disappearance curves (equation 8.1).

of muscle (126, 232). Anatomical studies of visceral capillaries also suggest a relatively high degree of porosity (13). Exchange rates of lipid-insoluble molecules between central nervous system tissue and blood are far lower than in peripheral tissues (68, 185, 357) although the anatomical site of the "blood-brain barrier" has not been localized with certainty to the capillary walls. Exchanges between blood and cerebrospinal fluid are complicated by absorption in bulk through large channels in the arachnoid villi and by specific active secretory mechanisms involving the choroid plexuses and ependymal linings of the ventricular system (279).

In spite of these regional differences in capillary permeability, it may be said that over-all bodily capillary permeability, determined from arterial disappearance rates of large molecules, does not differ greatly from that of isolated muscle. For example, the average plasma clearance ($\dot{n}/\Delta c$) of a dextran fraction of known free diffusion coefficient ($D = 0.10 \times 10^{-5} \text{ cm}^2 \text{sec}^{-1}$, $a = 32 \text{ Å}$) was found by Grotte (126) to be about .6 ml per min per kg dog or $10^{-3} \text{ ml per sec per 100 g tissue}$. From equation 7.6,

$$\frac{A_s}{\Delta x} = \frac{\dot{n}}{\Delta c} \div D = 10^{-3} \div .1 \times 10^{-5} = .01 \times 10^5 \text{ cm}$$

Application of the theory of restricted diffusion (equation 7.9) for average porosities of 40, 45, and 50 Å leads to true pore areas per unit path length of 1.4, 0.5, and $0.3 \times 10^{-5} \text{ cm per 100 g tissue}$, respectively.

These values, pertaining to over-all bodily permeability, may be compared with the value of $0.6 \times 10^5 \text{ cm per 100 g tissue}$ determined by the method of osmotic transient in isolated muscle (Fig. 9.2). The close correspondence between permeability to serum albumin computed from over-all arterial disappearance curves on the one hand and restricted diffusion through the capillaries of muscle on the other has already been noted (table 9.1). Similarly, the over-all bodily filtration coefficient is not greatly different from that determined in intact extremities or isolated perfused muscle (section 6). This correspondence between over-all capillary permeability and capillary permeability determined in isolated muscle is not too surprising since muscle accounts for some 65 per cent of total body weight exclusive of skeleton and fat which do not participate to a large extent in the capillary exchange.

10. MOLECULAR SIEVING OF LARGE MOLECULES: REGIONAL DIFFERENCES IN POROSITY

In artificial systems it is possible to apply high pressure differentials for rapid ultrafiltration, and under these conditions even small molecules can be "sieved" through porous membranes as illustrated in figure 7.4. In the capillary circulation, however, the transmembrane pressure differentials are necessarily small and no appreciable steady-state concentration differences of small molecules can be maintained, even at abnormally high rates of filtration. Substitution of approximate value of $A_m/\Delta x$ and r in equation 7.15 suggests that appreciable molecular sieving should be detectable with molecules of radius 10 to 15 Å at high rates of filtration caused by venous occlusion. This prediction has been verified in perfused hind limbs for the case of inulin ($a = 12-15 \text{ Å}$) during net filtration at the rate of 0.2 ml per min per 100 g tissue. Under these conditions the steady-state concentration of inulin in capillary filtrate was found to be 70 per cent of that in plasma (281); the theoretical value calculated from equation 7.15 is 77 per cent. In the case of still larger molecules, including the plasma proteins, the restriction to diffusion becomes sufficiently great to allow a high degree of molecular sieving, even at normal filtration rates.

Grotte (126) has carried out a detailed study of molecular sieving in relation to steady-state concentrations of large molecules in leg lymph, liver lymph, and cervical lymph. Grotte worked with dextran polymers of known free diffusion coefficient and mo-

FIG. 10.1. Molecular sieving of dextrans in leg lymph obtained from dogs. The results are in accord with the theory of molecular sieving (equation 7.15) through pores of radius 42 Å and for molecules up to 32 Å in radius. Increased lymph flow induced by venous congestion produced the expected increase in sieving. The unexpected passage of dextran molecules exceeding 40 Å in radius suggests an additional "large pore" system estimated by Grotte to comprise 1/30,000 of the total population of pores. [Adapted from Grotte (126).]

molecular radius. Figure 10.1, adapted from Grotte¹ shows lymph: plasma concentration ratios as a function of molecular radius at two different lymph flows. The theoretical curves for a capillary ultrafiltrate are drawn from equation 7.15, assuming a pore radius of 42 Å, that $A_w/\Delta x$ was constant and that capillary filtration rate was proportional to observed lymph flow. The agreement between theoretical and observed concentration ratios is surprisingly good for molecules up to about 32 Å in radius. However, the observed lymph concentrations of dextran molecules ranging in size from 50 to 90 Å cannot be explained on the basis of molecular sieving through pores of radius 42 Å. In order to explain capillary permeabil-

ity to these large molecules Grotte postulated the existence of large capillary leaks, corresponding to pores of radius 200 to 350 Å but comprising only 1 part in 30,000 of the total population of pores as computed by equation 7.16. In cervical lymph and liver lymph the molecular sieving curve was shifted to the right and the relative number of calculated capillary leaks was increased to 1 in 20,000 and 1 in 340, respectively.

Concerning the locations of these leaks or large pores along the length of the minute vessels very little is known. There is some evidence, however, that they may be more frequent in the walls of venous capillaries and venules than in the walls of true capillaries. In recent studies (Landis, unpublished) solutions of T-1824 in Ringer's solution, with and without protein, have been perfused by microinjection through single vessels or through portions of peripheral networks in the frog's mesentery. Motion pictures (25–40 frames per sec) reveal sites at which the dye solutions pass rapidly through the vessel wall during the first few seconds of perfusion (fig. 10.2). In true capillaries the loci of such early, spotty passage of dye are few in number; the extravascular spots of dye are small in size and distinct in outline. In venous capillaries and venules the loci of passage are more numerous; the extravascular spots of dye tend to be larger and, particularly around venules, often coalescent. It seems likely, therefore, that while the small pore system is uniformly distributed throughout the capillary network, the leak or large pore system is more prominent in the venous capillaries and venules. A differential distribution of this type helps explain earlier work (reviewed in detail in ref. 207) on the spotty passage of certain dyes through the walls of true capillaries (200, 262) and on the gradient of permeability to poorly diffusible dyes described by Rous and co-workers (e.g., 161, 307, 308, 337, 338).

Results similar to those obtained by Grotte (126)

FIG. 10.2. Distribution of "leaks," "large pores" or gaps in the walls of the minute vessels of frog's mesentery as indicated by cinephotomicrographs of rapid, spotty passage of T-1824 (Evans blue dye). With camera running at the rate of 25 frames per sec, the dye solution was perfused through the capillary network from a micropipette introduced into the terminal, feeding arteriole. From the film thus obtained single frames have been removed to show sites and extent of dye passage at intervals of seconds (e.g., 1", 2", 3", etc.) timed from that frame in which the dye had first filled the capillaries (labeled O). The frames labeled C show the network before dye entry; those labeled 2' and C₂ after the perfusion was ended to indicate absence of stasis and hence absence of detectable injury.

Left: perfusion of .01 M T-1824 freshly prepared in frog Ringer's solution. Top section (magnification $\times 17$) shows progression of spotty passage involving true capillaries, a venous capillary and a minute venule. Middle and lower sections show greater detail (magnification $\times 60$) at 2 sec and 12 sec, respectively. *Right:* perfusion of .01 M T-1824, and 3 g/100 mg albumin, in frog Ringer's solution. Top section (magnification $\times 35$) shows spotty passage in true capillaries and a venous capillary. Middle and lower sections show greater detail (magnification $\times 120$) at 2 sec and 12 sec, respectively. Rapid, spotty passage of perfused dye persisted despite protein binding. In general, however, protein binding made spots of passage more discrete.

FIG. 10.2. See legend on facing page.

have been reported by Mayerson *et al.* (232) who found that dextran fractions of mean molecular weights greater than about 100,000 ($a > 60 \text{ \AA}$) appear in hepatic, intestinal, and cervical lymph in concentrations which are almost independent of molecular size. Mayerson *et al.* follow Grotte in ascribing these results to the presence of large capillary leaks but they also mention an interesting alternative possibility that very large molecules may be transported by active endothelial vesiculation (pinocytosis) as described by Palade (273) and Moore & Ruska (255). In calculating pore-size distributions Mayerson *et al.* do not take into account sieving effects nor the fact that filtration varies with the fourth power of pore radius. They assume that filtration rate through pores of given collective area will be the same, regardless of pore radius. If 5 per cent or more of the capillary pores had a radius $> 200 \text{ \AA}$, as suggested by Mayerson *et al.*, then from equation 7.16

$$\bar{r} > \sqrt[4]{0.5(200 \times 10^{-8})^4} > 95 \text{ \AA}$$

A mean pore radius of 95 \AA for hydrodynamic flow would lead to an improbably high value for the filtration coefficient. For this reason we favor Grotte's interpretation in terms of molecular sieving through pores of radius 40 to 45 \AA combined with relatively few large capillary leaks. Both interpretations are subject to the criticism that lymph is not a capillary ultrafiltrate and may well be modified by capillary reabsorption (208), particularly at low rates of lymph flow.

A more clear-cut application of the theory of molecular sieving is possible in the case of renal glomerular membranes. Figure 10.3 shows the glomerular clearances of several proteins and dextrans relative to creatinine in the dog. The apparent differences between glomerular sieving of dextran molecules and proteins of equivalent molecular radius may be spurious because the dextran fractions were not perfectly monodisperse and it is possible that the lesser degree of sieving for each nominal molecular radius represents the contribution of smaller dextran molecules. The data agree well with theoretical curves for molecular sieving through an isoporous membrane having pores 35 to 42 \AA in radius and a total pore area per unit path length for water of $1.6 \times 10^5 \text{ cm}^2 \text{ per g kidney}$ (278). Substitution of these values in equation 7.13 leads to filtration coefficients in the range $3.5 \text{ to } 5.0 \times 10^{-5} \text{ cm}^3 \text{ dyne}^{-1} \text{ sec}^{-1} \text{ per g}$ or 2.7 to 3.9 ml per min per mm Hg per 100 g kidney. These values are in excellent agreement with estimates based on hemodynamic data (339, 384). Almost identical values for renal glomerular permeability have also been derived by Lambert and his associates (194-196) from molecular sieving of hemoglobin as a function of glomerular filtration rate.

The greater permeability of renal glomerular membranes relative to peripheral capillaries is evidently due to a relatively large fractional pore area rather than to large pores. Given a path length for filtration and diffusion of $0.5 \times 10^{-4} \text{ cm}$, the glomerular pore area for passage of water would be $8 \text{ cm}^2 \text{ per g}$

FIG. 10.3. Theoretical vs. actual molecular sieving through renal glomerular membranes of dogs. Molecular sieving of myoglobin, egg albumin, and hemoglobin calculated as in references 278 and 194. Data for dextran fractions are taken from Wallenius (366).

kidney or 5 to 10 per cent of the available glomerular surface estimated histologically by Vimtrup (360).

Recent studies of glomerular ultrastructure suggest that the anatomical basis for glomerular sieving is not in the fenestrated capillary endothelium, but rather in the epithelial cells (podocytes) covering glomerular capillaries. According to Hall (141) these cells form foot processes which approximate the endothelial basement membranes in such fashion as to form interdigitating "slit-pores" which appear to be 80 to 100 Å wide and occupy 2 to 3 per cent of the total surface.

II. CAPILLARY PERMEABILITY TO LIPID-SOLUBLE MOLECULES; RESPIRATORY GASES

Capillary permeability to lipid-soluble molecules has been studied by Renkin (296, 297) using the perfused hind-limb preparation. Urethan (mol wt 89), paraldehyde (mol wt 132) and triacetin (mol wt 218) traversed the capillary walls so rapidly that no osmotic transients were detectable (figure 11.1). Glycerol and acetic esters of glycerol were shown to pass through capillary walls at high rates which varied in order of their oil: water partition coefficients but in order opposite to that expected on the basis of their aqueous diffusion coefficients. The temperature coefficients of capillary permeability to antipyrine and antipyrine derivatives were found to be related to the temperature coefficients of their lipid solubilities rather than to their aqueous diffusion coefficients.

These results suggest that lipid-soluble molecules can diffuse through regions in the capillary wall which are relatively impermeable to lipid-insoluble materials. The permeability characteristics of this

additional pathway are similar to those of cell membranes in general. It seems logical, therefore, to identify the diffusion pathway for lipid-soluble molecules with the plasma membranes of the capillary endothelial cells themselves, as opposed to the system of water-filled pores penetrating through or between these cells, which is capable of accounting for passage of water and lipid-insoluble molecules.

The respiratory gases have relatively large oil: water partition coefficients (212) and may therefore be expected to utilize the entire endothelial surface for the transepithelial diffusion process. Recent measurements of pulmonary diffusing capacity (306) indicate that permeability of human alveolar membranes (alveolar capillaries plus alveolar epithelium) is approximately 60 ml O₂ per min per mm Hg O₂ pressure difference. In terms of oxygen concentration difference, this value becomes $0.4 \times 10^5 \text{ cm}^3 \text{ sec}^{-1}$ (i.e., ml/sec/ml concentration difference). The capillary surface area in the lungs is approximately $4 \times 10^5 \text{ cm}^2$ (258), whence the specific permeability coefficient for oxygen is $10,000 \times 10^{-5} \text{ cm sec}^{-1}$. This value may be compared with $23 \times 10^{-5} \text{ cm sec}^{-1}$, representing the specific permeability of muscle capillaries to water (table 9.1). Presumably the greater permeability to oxygen is a result of lipid solubility, since the pulmonary capillaries resemble peripheral capillaries in being relatively impermeable to small lipid-insoluble molecules (378). In 100 g of quiescent muscle containing a capillary surface area of 5,000–10,000 cm² the steady-state flow of oxygen across the capillary walls is about 0.4 ml per min (fig. 12.2). During maximal muscular activity the oxygen requirements increase 20-fold to 30-fold and the available capillary surface may increase 2-fold to 4-fold.

FIG. 11.1. Osmotic transients produced by urethan and urea in an isolated perfused cat hind limb. pCi = isogravimetric capillary pressure. P_p = protein osmotic pressure in perfusion fluid. 36 mM/liter of urea produced a large osmotic transient owing to restricted diffusion of urea through the capillary walls. Urethan, despite its larger molecular size, failed to produce a detectable osmotic effect. The results are attributed to the greater lipid solubility of urethan which enables it to diffuse through the entire capillary endothelial surface. [From Renkin (296).]

If the specific permeability of muscle capillaries for oxygen were comparable with that of alveolar membranes, then transcapillary oxygen pressure differences of 0.3 to 0.6 mm Hg and 3 to 8 mm Hg would suffice to account for observed rates of tissue oxygen consumption at rest and during maximal work, respectively. For CO_2 the corresponding values are 20-fold smaller owing to its greater solubility. It therefore seems unlikely that capillary permeability is an important factor limiting the exchange rates of respiratory gases, except possibly during maximal muscular activity.

12. CAPILLARY PERMEABILITY AND BLOOD FLOW IN RELATION TO EXCHANGE OF MATERIALS BETWEEN BLOOD AND TISSUES

In previous sections evidence was reviewed showing that lipid-soluble molecules and small lipid-insoluble molecules or ions diffuse back and forth across capillary walls at rates which greatly exceed rates at which these substances are brought to or from the tissues by the blood. For such substances capillary permeability is clearly not an essential factor determining net rates of blood-tissue exchange. Other more essential factors include the distribution and rate of flow of capillary blood, the volume and permeability of extravascular distribution compartments, and rates of chemical reaction in the tissues. For molecules of intermediate size, including products of intermediary metabolism, capillary permeability may become more important but is still only one of the several factors determining over-all kinetics of the exchange process. Only in the case of relatively large molecules (e.g., inulin or larger) can capillary permeability be considered as a primary factor limiting exchange with well-perfused tissues.

Mathematical descriptions of diffusion kinetics in the capillary circulation are included in papers by Krogh (183), Hill (153, 154), Kety (173, 174), Opitz & Schneider (269), Morales & Smith (256), Schmidt (318, 319), Sangren & Sheppard (310), Renkin (300), and Blum (19). Each of these mathematical descriptions is based upon a particular model of capillary-tissue geometry and each involves simplifying assumptions concerning permeability which do not apply to all molecular species. Such models are nevertheless useful, if only to provide a definite hypothesis with which experimental results may be compared. Examples illustrating the use of such models are given below.

A. Blood-Tissue Transport of Oxygen

The essential role of the capillaries in the blood-tissue exchange of respiratory gases was considered by Krogh (183) in terms of spatial distribution of blood vessels relative to tissue metabolism. Krogh proposed a simple model in which each capillary of radius, r , supplied a cylinder of tissue of radius R . The intercapillary distance was therefore $2R$ and the number of capillaries per cm^2 was $(1/2R)^2$. It was assumed that rate of tissue metabolism would be uniform throughout the cylinder and that the diffusion coefficients of gases through the cylinder would be uniform and identical with values measured in dead tissues. The mathematical solution for steady-state radial diffusion under these conditions was derived for Krogh by Erlang (183) and has formed the starting point for many subsequent discussions of the blood-tissue exchange of gases [cf (174) for contemporary review].

Figure 12.1 is a graph of the Krogh-Erlang equation for capillaries of radius 4μ ; the equation is relatively insensitive to values of r and for all practical purposes the same graph applies to capillaries of radii 3 to 5μ . This model suggests that as few as 25 open capillaries per mm^2 would suffice to supply the oxygen requirements of resting muscle without exceeding the limiting diffusion pressure head set by oxygen in venous blood (i.e., a finite oxygen pressure would exist even in the outermost region of the diffusion cylinder surrounding each capillary). The corresponding figure for maximal muscular activity is 500 capillaries per mm^2 . Brain and liver would require 200 and 100 capillaries per mm^2 , respectively. Estimates of capillary density usually exceed these values by a wide margin and suggest that the oxygen pressure head required to supply the diffusion cylinder around each capillary is far less than that available in capillary blood, even at maximal rates of tissue metabolism.

Capillary counts on injected muscles from anesthetized animals lead to estimates in the range 200 to 600 per mm^2 for resting muscle and 600 to 5000 per mm^2 for contracting muscle (84, 143, 183, 227, 272, 284, 320, 335, 353). There is considerable variation among skeletal muscle, heart (305), and abdominal wall muscle (184) representing examples of high and low density, respectively. In general, muscles from small animals have a higher capillary density than from large animals (320). In maximal vasodilatation there is often a 1:1 relation between number of capillaries and number of muscle fibers, but maximum capillary density can be increased by exposure to high altitudes or by daily physical exercise (358). Capillary counts made on fixed preparations tend to be high because of shrinkage artifact; in frozen sections the muscle fibers are larger and estimated capillary densities smaller. In the author's experience, 150–200 capillaries per mm^2 is

FIG. 12.1. Steady-state radial diffusion of oxygen (\dot{Q}_{O_2}) as a function of capillary density (*abscissa*) and radial oxygen pressure gradient from capillaries to tissue (*ordinate*). [Graph constructed from the Krogh-Erlang equation (183).]

- P_C , capillary O_2 pressure, mm Hg
 P_R , tissue O_2 pressure at R
 \dot{Q}_{O_2} , O_2 consumption, ml/sec per ml tissue
 α , O_2 solubility = 2.8×10^{-5} ml/ml \times mm Hg $^{-1}$
 D , tissue O_2 diffusion coeff. = 1.5×10^{-5} cm 2 /sec ()
 R , radius of diffusion cylinder
 r , capillary radius = 4μ

usual in frozen sections of muscles from hind limbs of anesthetized cats. Many of the higher estimates imply capillary blood volumes in the range 5 to 15 per cent of tissue volume. In most skeletal muscles the entire blood volume is less than 4 per cent of tissue volume (328, 335) and at least half of this may be accounted for by large blood vessels (243). Even taking low estimates for capillary density, however, (200/mm 2 at rest, 600/mm 2 in activity) the oxygen pressure gradient predicted by the Krogh-Erlang model would be less than 5 mm Hg at rest and less than 20 mm Hg in maximum work, leading to tissue oxygen pressures of 10 to 30 mm Hg in the outermost regions of each diffusion cylinder.

The Krogh-Erlang model provides a theoretical basis for analysis of the blood-tissue gas exchange, but several lines of evidence suggest that factors other than simple radial diffusion in a homogeneous medium may be involved. In the case of skeletal muscle, Milli-

kan (253) showed that intracellular myoglobin rapidly becomes desaturated during contraction of the soleus muscle in the cat. Since the half saturation pressure of myoglobin at physiological pH is only 3 mm Hg this implies that intracellular oxygen tension falls to extremely low values during contraction. Lactic acid increases rapidly in venous blood from contracting muscle (7, 181), also indicating that oxygen supply cannot keep up with demand at high rates of metabolism, despite normal oxygen pressures in venous blood. Mechanical reduction of blood flow to resting muscle may cause substantial reduction of steady-state oxygen consumption even when the blood vessels are dilated and when venous oxygen pressure is sufficiently high to meet the diffusion requirements estimated from the Krogh-Erlang model (275, 359) (fig. 12.2). Inter-

capillary oxygen pressures may be extremely low in brain (64) despite normal oxygen pressures in cerebral venous blood. The critical venous oxygen pressure at which brain suffers a decrease in oxygen consumption is 20 to 25 mm Hg (269); presumably, under these conditions, oxygen pressure is zero in regions most remote from the capillaries.

These observations suggest that the gradient of oxygen pressure from capillary blood to tissues is greater than predicted from the simplified model proposed by Krogh. One factor neglected by Krogh's treatment of the problem is the rate at which oxygen can be released from red cells during their brief exposure to the tissues in capillary blood. Roughton & Forster (306) and Forster (108) have recently discussed evidence that chemical reaction velocity and diffusion in the red cell account for almost one-half the total resistance to transfer of oxygen between alveolar gas and blood. The rate of dissociation of oxygen from hemoglobin is slower than its rate of combination and recent measurements by Niesel *et al.* (261) and Thews (356) indicate that the intracapillary component of oxygen diffusion may be a major factor limiting the rate at which oxygen can be supplied to adjoining tissues. This factor could be evaluated experimentally and deserves attention in future studies of the blood-tissue exchange of gases. Scholander's recent demonstration of facilitated diffusion of oxygen through thin films of hemoglobin or myoglobin (321) may also be of significance for diffusion of oxygen in muscle, especially cardiac muscle.

B. Blood-Tissue Exchange of Small, Nonmetabolized Molecules or Ions

A simple model of blood-tissue exchange has been employed by Renkin (299, 300) to describe diffusion kinetics of urea, antipyrine, sucrose, and K^{42} in perfused muscle. This model is particularly useful for illustrating the relative effects of permeability and blood flow on diffusion kinetics in uniformly perfused tissue. In its simplest form the model assumes two compartments representing total blood volume, V_1 , and extravascular distribution volume, V_2 . The compartments are separated by a barrier of virtual area A_m and permeability coefficient, P . V_1 is allowed to flow past the barrier at rate, \dot{Q} . V_2 is assumed to be homogeneous with respect to concentration of diffusing materials. The mathematical solution for this model (300) is given by

$$C = \lambda \frac{V_1 V_2}{(V_1 + V_2)} = \dot{Q} \left(1 - e^{-\frac{PA_m}{\dot{Q}}} \right) \quad (12.1)$$

where C = clearance from the blood compartment, V_1 , ml per min, and λ = slope of the exponential disappearance curve from the blood compartment, min^{-1} . In perfused preparations the rate of blood flow may be varied over a wide range by simple adjustment of perfusion pressure. Clearance, C , from the perfusion reservoir can be measured accurately. It is therefore possible to determine over-all permeability, $P \times A_m$, of barriers separating blood from the final distribution volume, provided the original assumption of uniform distribution in extravascular space is correct. For many substances this assumption will not be valid and in such cases PA_m must be considered as a virtual permeability which includes the effects of nonuniform distribution in extravascular space.

Figure 12.3 shows capillary clearances of antipyrine, K^{42} and urea as a function of blood flow in widely dilated blood vessels of mammalian muscle. The changes in blood flow were produced by change of arterial perfusion pressure and presumably reflect changes in flow velocity through a constant capillary surface as required by the model. Comparison of the results with theoretical curves drawn from equation 12.1, suggest blood-tissue permeabilities (PA_m) of about 3 and 10 ml per min per 100 g muscle for urea and K^{42} , respectively. For antipyrine the observed capillary clearances were equal to blood flow, indicating that for this (lipid-soluble) substance permeability (PA_m) was large with respect to blood flow.

Blood-tissue permeabilities estimated by equation 12.1 from measurements of blood flow and clearances are compared in table 12.1, with capillary permeability estimated from osmotic transients and the theory of restricted diffusion. In the case of sucrose the blood-tissue permeability is 30 to 60 per cent of capillary permeability. Sucrose distributes primarily in interstitial fluid and the only barriers to diffusion are capillary walls and interstitial fluid volume. From the available data (table 12.1) it appears that in muscle about one-half the total resistance to distribution is located in the capillary wall. Cotlove (46) has shown that distribution rates of NaCl, sucrose, and inulin into connective tissue spaces of extremities are limited by the long path length for diffusion along fascial planes and by retardation of diffusion in the interstitial matrix. Recent measurements by Ogston & Sherman (266) indicate that diffusion of molecules as small as glucose may be appreciably restricted in dilute gels formed by hyaluronic acid and the action of hyaluronidase in reducing resistance to flow through connective tissue has been described by Day (69).

FIG. 12.2. Steady-state oxygen consumption as a function of blood flow and tissue temperature in the hind limb muscles of an anesthetized cat. Oxygen consumption was lowered when oxygen supply (blood flow) was reduced below a critical value at each temperature. Critical oxygen pressures in venous blood were 40, 28, and 16 mm Hg at oxygen consumptions of 0.3, 0.15, and 0.06 ml/min respectively. A capillary-tissue pressure gradient of less than 5 mm Hg would suffice to supply these rates of oxygen utilization by simple radial diffusion in tissue containing 100 perfused capillaries per mm: (fig. 12.1). The results indicate that the gradient of oxygen pressure from capillary blood to tissue is greater than that predicted from the simplified model proposed by Krogh (183). Oxygen saturation, S , measured by oximeter and gas analysis. Oxygen pressure in venous blood, $P_{V_{O_2}}$, estimated from measured oxygen dissociation curves at each temperature. Tissue temperature adjusted by passing femoral arterial blood through a heat exchanger. Blood flow adjusted by variable arterial resistance. (From unpublished experiments by Rapela *et al.*)

Urea and K^{42} distribute in intracellular water and for these substances the chief barrier to diffusion is probably located at cell membranes in the tissues. Table 12.1 shows that blood-tissue permeabilities to these substances are far less than respective capillary permeabilities.

When blood-tissue permeability is large with respect to blood flow, equation 12.1 approaches the limit $C = Q$ and blood-tissue distribution is said to be flow limited. This is the case for lipid-soluble molecules in general (e.g., antipyrine, fig. 12.3) and provides the theoretical basis for estimating regional blood flow from blood or tissue clearances of these substances (173). Johnson *et al.* (168) have shown that distribution of labeled water is blood flow limited in cardiac and skeletal muscle and Sapirstein (311) has used the

blood clearances of Rb^{86} or K^{42} as a measure of relative regional blood flow. The clearances of labeled Na or I from blood or interstitial space have also been used for this purpose (72, 165, 172, 290, 362) but in view of the interstitial component of blood-tissue permeability this may not be justified. Several investigators have measured fractional extractions (C/Q) of test materials during single passage through vascular beds of extremities (40, 111), head (40), liver (40), heart (44) and lungs (39). Equation 12.1 suggests that the values so obtained reflect the exponential ratios of blood-tissue permeability to blood flow under the conditions of vascular tone prevailing at the time of measurement.

For large lipid molecules the chief barrier to tissue distribution is the capillary wall and in this case PA_m

FIG. 12.3. Diffusion kinetics of antipyrine, K^{42} , and urea in vasodilated muscle. Permeability to antipyrine (lipid-soluble) is so large that its clearance is limited by rate of blood flow. The clearances of K^{42} and urea are limited, in part, by permeability of cell membranes in extravascular distribution volume. Less than 10% of the diffusion barrier to urea is contributed by the capillary wall (table 12.1). [Adapted from Renkin (299, 300).]

TABLE 12.1. Comparison of Blood-Tissue Permeability with Capillary Permeability

| Substance | Permeability, ml/min/100 g Muscle | |
|-----------|-----------------------------------|----------------------------------------------|
| | Blood-tissue PA_m^* | Capillary walls $D_s A_s / \Delta x^\dagger$ |
| Sucrose | 5-11 | 18 |
| Urea | 4 ± 2 | 54 |
| K^{42} | 7 ± 3 | 90 |

* From equation 12.1 † From table 9.1.

$= D_s A_s / \Delta x$. For these substances PA_m is small compared to normal rates of blood flow and equation 12.1 reduces to equation 8.1 describing arterial disappearance curves of large molecules.

C. Nonuniform Distribution of Blood Flow in Relation to Blood-Tissue Exchange

The model discussed in the previous paragraphs was designed to simulate effects of changes in flow velocity through a constant number of open capillaries and the results illustrated in figure 12.1 refer to widely dilated blood vessels. At any given over-all blood flow, the clearance of test molecules may be very much smaller during vasoconstriction (299, 300). In supine, anesthetized dogs the fractional extraction of antipyrine or D_2O from the circulation to extremities may be only 0.6 to 0.8 (40) in contrast to values close to unity

in perfused, vasodilated muscle (168) or the intact human forearm (111). The fraction of total blood flow passing through true (nutrient) capillaries is subject to wide variation according to metabolic demands of the tissue or to hemodynamic demands of the organism as a whole. In some tissues, such as skin, liver, or intestine, the nonnutrient fraction of total blood flow may pass through arteriovenous anastomoses of potentially large caliber; in other tissues, such as mesentery or muscle, effective physiological shunts are formed by arteriovenous capillaries (388). Nonuniform distribution of blood flow within single organs may also occur between regions of different function and metabolic rate, examples being medulla and cortex of the kidney or gray and white matter of the central nervous system.

It is obvious that nonuniform alterations of blood flow in the microcirculation will change the relations between total blood flow and blood-tissue exchange rates; conversely, it may be anticipated that quantitative studies of effective tissue perfusion will depend heavily upon information obtained from exchange rates. At the present time, available information is mostly qualitative and derives in large part from observations on muscle.

A striking example of nonuniform distribution of blood flow in skeletal muscle can be observed following electrical or reflex stimulation of sympathetic vasoconstrictor nerves. Closure of precapillary sphincters,

innervated by the sympathetic vasoconstrictor system, can stop nutrient blood flow through large areas of capillary bed, leaving blood to flow through arteriovenous thoroughfare channels or other regions of low metabolic rate. Under these conditions, total blood flow is reduced but oxygen saturation of venous blood approaches that of arterial blood (26, 274, 294) and respiratory gas exchange may be reduced to one-half or less of its normal value. In diving mammals, drastic vasoconstriction of this type greatly reduces tissue gas exchange for periods of one-half hour or more (322, 323). This is in contrast to uniform reduction of total blood flow caused by decrease in arterial pressure or infusion of vasoconstrictor drugs (274); under these conditions, oxygen extraction is increased and oxygen utilization remains relatively constant over a wide range of blood flow (fig. 12.2).

Recent investigations of the rates at which labeled ions are removed from interstitial space in muscle also suggest that vasomotor nerves control the distribution of blood between nutrient and nonnutrient circulations (165). There is general correspondence between clearance of Na^{24} or I^{131} and over-all blood flow when flow is altered by pressure, reactive hyperemia, or

exercise (72, 165, 172, 290, 362). However, activation of the vasomotor system to muscle or skin generally results in large changes of flow without corresponding changes of clearance. Hyman *et al.* (165) have shown that I^{131} clearance may actually decrease during large increases of flow caused by activation of the sympathetic vasodilator system. They suggest that vasodilator nerves act primarily to increase flow through arteriovenous thoroughfare channels.

Studies of this type are only beginning and they point to new directions for research on the peripheral circulation. The principal function of the circulation is to provide for exchange of materials between blood and tissues and it seems logical to study this function directly in terms of exchange rates. Such studies will only be meaningful, however, if the limitations imposed by over-all permeability are considered in relation to tissue perfusion. In the present article we have provided a quantitative background for assessing the role played by capillary permeability in the distribution process, indicating only briefly the contributions of interstitial diffusion, cellular permeability, or chemical reaction velocity.

FROM A PHYSIOLOGIC point of view, the lymphatic system is primarily a drainage system. Its need arose phylogenetically with the development of a high pressure circulation. The latter development, designed to insure an adequate supply of oxygen to

tissues, created a situation favoring transudation of fluid and other substances from the capillaries. An increase in plasma protein served to counteract partially this leakage, since the plasma proteins exerted an osmotic pressure. There still remained, however, the problem of clearing the tissue spaces of substances which had leaked out of blood capillaries or which were not absorbed into the blood stream. In this sense, the lymphatic system must be regarded as a homeostatic mechanism, important in the maintenance of the constancy of the *milieu interieur*. It is this point of view that will be emphasized in the present discussion. The role of the lymphatic system in the transport of materials from the liver and intestines to the blood stream will also be considered. No attempt will be made to cover all that has been done regarding lymph and lymphatics nor will the extensive literature on lymph nodes and lymphoid tissues be discussed. Various aspects of the general subject have been treated in depth during the last several decades in reviews and monographs (45, 58-60, 62, 66, 88, 135-137, 185, 189, 215, 223, 227, 234) and the reader is referred to these sources for basic material not included in the present review. Two recent monographs will be found most helpful (189, 234). The latter source will interest those concerned with clinical implications of disturbed lymphatic function. It also includes results of work in Hungarian and Russian laboratories not readily available in the English literature.

METHODS OF STUDY

Although lymphatics presumably had been seen by members of the Alexandrian school (Herophilos,

¹ The work described as emanating from this laboratory was supported by grants from the Research and Development Command, U. S. Army, the American Heart Association, and the U. S. Public Health Service.

300 B.C.; Erasistratus, 310–250 B.C.) the documented study of lymphatics dates from 1622, when Asellius (3) demonstrated “lacteals” in the mesentery of a well-fed dog and at a later date had the opportunity of observing these channels in a criminal who had been executed following a large meal. Jean Pecquet (169) in 1651 described the cisterna chyli and the thoracic duct. The term “lymphatics” was first used by Thomas Bartholin (12, 13) and he and Rudbeck (186) are usually considered to be the co-discoverers of the lymphatic system.² In 1692 Nuck (160) introduced the use of mercury for injection of lymphatic vessels, a method which was used extensively by many investigators during the eighteenth century to describe the location and distribution of the main lymphatic vessels. Of particular importance was the work of Hewson (99), a pupil of William Hunter, who made extensive dissections of the lymphatic system and noted that lymph glands were absent in fishes (also in the turtle), few in number in birds, and well developed only in mammals. He also noted the presence of lymphocytes in lymph and thought they came from lymph glands to enter blood via the lymph channels. Hunter himself speculated that “the lymphatic vessels are the absorbing vessels, all over the body” (101).

Anatomical studies during the nineteenth century further delineated the distribution and characteristics of the lymphatic supply of various organs (194), but it remained for Ludwig (129) and Heidenhain (96) to provide the stimulus for studies of function. Ludwig developed techniques for the collection of lymph by cannulating lymph vessels in different parts of the body. He contended that lymph was a filtrate derived from blood, a point of view contested by Heidenhain who maintained that it was actively secreted by the lymphatic epithelium. This classic controversy was finally settled by the extensive work of Starling during the first part of this century (203), who demonstrated the relationships between hydrostatic and osmotic pressures in the exchange of substances between plasma and lymph, concepts still fundamental and generally applicable. These relationships have been discussed in Chapter 29.

The study of lymph and lymphatics has lagged behind that of other parts of the circulation because of inherent difficulties in identification and dissection of the lymphatics and their cannulation. Since

lymph is virtually colorless, it does not help in the visualization of these small vessels. Even the identification and dissection of the largest trunk, the thoracic duct, is a formidable challenge to the uninitiated investigator unless its visualization is aided by previous injection of dyes or feeding of fats. Once identified and dissected, cannulation of a lymphatic still presents a problem because of the ease with which the thin vessel can be torn. This may explain the temptation for investigators to forsake the actual collection of lymph for the much less frustrating study of the effects of ligation of the vessels. Rudbeck expressed these difficulties very well in 1653 when he said:

“Of the many structures difficult to find in anatomical dissections, these vessels, I must confess, are by no means the least. For usually they will not tolerate the finest blunt probe, a sharp knife, a suction tube, or any other instrument whatever. And even though abundantly present, they are often obscured by fat, or are overlooked if not at the moment filled with fluid. When seen they may disappear if not ligated. Thus in elusiveness they rival the lacteals and must be handled with utmost care.”

Several recent developments have, however, made the lives of the lymphatic investigators less trying and their labors more rewarding. Availability of nontoxic and radiopaque dyes has facilitated tracing of lymphatic pathways and stimulated a new interest in this aspect, particularly in surgery (20, 52, 112). To the physiologist, the greatest boons have been the availability of polyethylene tubing and isotopes. The range of sizes and flexibility of polyethylene tubing and relative freedom from clotting in this tubing have made cannulation easier and have made chronic experiments possible not only in unanesthetized experimental animals but in man (16, 31, 54, 125, 177, 201, 208). Small vessels entered with glass cannulae only with the greatest difficulty can now be studied (198, 199). The use of isotopes has facilitated the study of lymphatic uptake from subcutaneous tissues (100, 209). It has also made possible more quantitative studies on the exchange of substances between plasma and lymph. These gains will be apparent in the discussions to follow.

DEVELOPMENT AND STRUCTURE OF LYMPHATIC VESSELS

It is now generally agreed that lymphatic vessels are derived from veins. To quote Sabin (190) “Lym-

² There is an interesting biographical note by G. Liljestrand and a translation of Rudbeck's “*Nova exercitatio anatomica*” by A. E. Nielsen in the *Bulletin of the History of Medicine* 11: 304–339, 1942.

phatics are modified veins. They are vessels lined by an endothelium which is derived from the veins. They invade the body as do blood vessels and grow into certain constant areas; their invasion of the body is, however, not complete for there are certain structures which never receive them. The lymphatic capillaries have the same relation to tissue spaces as have blood capillaries. None of the cavities of the mesoderm, such as the peritoneal cavity, the various bursae and serous capillaries, forms any part of the lymphatic system. The lymphatic endothelium once formed is specific. Like blood vessels the lymphatics are for the most part closed vessels."

The lymphatic capillaries may be considered as endothelial tubes resembling blood capillaries but thinner. The medium-size vessels (100–200 μ) have muscle fibers, whereas the larger lymphatics are composed of an endothelial layer covered by a diffuse connective tissue sheath in which elastic and muscular elements are irregularly scattered. Amyelinated nerves can be traced to the muscle fibers. Valves develop during intra-uterine life in the large vessels and are usually unicuspid or bicuspid. These structures determine the direction of flow toward sites of emptying into the blood stream.

LYMPH VS. TISSUE FLUID

It is now generally accepted, primarily from the work of Sabin (191) and MacCallum (132), that the lymphatics form a closed system. "Lymph," therefore, is not synonymous with "tissue fluid," but is the fluid found in lymphatics. This is more than a semantic distinction because, as will be apparent later, the composition of lymph is more particularly determined by the permeability of blood capillaries in a definite area and the consequent pericapillary filtrate than it is by the metabolism of tissue cells. In this sense, lymph is pericapillary filtrate which has mixed with tissue fluid and has entered the closed lymphatic system.

Clark & Clark (43) showed that lymphatic capillaries are sometimes closely associated with small blood vessels, with virtually nothing between the two membranes, while in other cases they bear no relationship to such vessels. In any region, the fluid that enters the lymphatic system to become lymph may be that which is adjacent to the arterial end or to the venular end of a blood capillary, or it may be fluid that is relatively distant from a blood capillary. McMaster (137) studied the relative pressures within

the cutaneous lymphatic capillaries and the surrounding tissues in the mouse's ear. He reported that the mean lymphatic pressure was 1.2 cm water and the interstitial pressure 1.9 cm water. There was always a gradient of pressure from the interstitial tissue to the lumen of the lymphatic even in conditions of increased lymphatic pressure. Presumably, whenever increased amounts of fluid are present in the interstitial tissues, the lymphatic vessels are kept open by swelling of connective tissues and increase in the tension of the fibers attached to the lymphatic capillaries (42, 43, 137, 175). Many more data are needed in other tissues and species to establish firmly the fact that a gradient of pressure is always present between interstitial tissues and the lymphatics, and is an important factor in the formation of lymph. Particularly disturbing in this connection is the recent report of Guyton *et al.* (93) suggesting the existence of negative pressures in interstitial spaces.

The close anatomical relationship between the lymphatic and venous systems has raised the question as to the relationship of lymphatic and venous pressures. Little definitive information is available, however, in this area, due primarily to the difficulties in measurement of lymphatic pressure. Many of the pressures that have been recorded are end pressures (234) and not particularly representative of the actual pressures under normal conditions of flow. Thus, Lee (124) found the average end thoracic duct pressure in dogs to be 15 cm H₂O, whereas Rouviere & Valette (185) found side pressure at the entrance to the subclavian vein to be 6.4 cm H₂O. They also found the pressure in the internal jugular vein of the same animal to be 2.4 cm H₂O, thus demonstrating the existence of a gradient capable of promoting emptying of lymph from the thoracic duct to the jugular vein. Webb & Starzl (222) found side pressures of 3.5 to 5.5 cm H₂O in the thoracic duct just above the diaphragm in anesthetized dogs. At this point, arterial pulsations affected the lymph pressure, the difference between the pressures during systole and diastole being 2 to 3 cm H₂O. Although these values are lower than those of Rouviere and Valette, they still permit of a gradient toward the vein. Irisawa & Rushmer (103) recently reported on the relationship between lymphatic and venous pressure in the legs of dogs. Although previous investigators had regarded lymphatic pressure of a resting dog leg as being too low to measure, these authors, working with unanesthetized dogs, found the leg lymphatic pressures to range from 2.5 to 12.0 cm H₂O, while the range of pressures in ankle veins was from 5.5 to

15 cm H₂O. Pressure levels in veins and lymphatics were generally very similar at rest, the venous pressures being only slightly higher. It would thus seem that pressure in the lymphatic capillaries may be comparable to the pressure in the venous end of capillaries at rest. These authors found the leg lymphatic pressure to fluctuate with respiration. With increased venous pressures, lymphatic pressure rose slowly but never reached the level of venous pressure, a reflection, perhaps, of the distensibility of lymphatics (156) and collection of fluid in the tissues. Similar experiments in our laboratory (Miller, unpublished) on the anesthetized dog also showed a lack of direct correspondence between leg lymphatic and venous pressures under a variety of experimental procedures.

DISTRIBUTION OF LYMPHATIC VESSELS

Although lymphatic capillaries spread into a tissue after the blood vessels, the density of the lymphatic plexus does not always run parallel with the richness of the blood supply. Furthermore, capillary plexuses vary tremendously in richness in different organs and tissues. For example, they are abundant in the dermis, the conjunctiva, the periosteum of bone, and in the mucosa and submucosa of the alimentary, respiratory, and genitourinary tracts, but are presumably absent in cartilage, bone marrow, the central nervous system, epithelium, and fetal part of the placenta (62). Voluntary muscle contains lymphatics only in fascial planes. It is generally believed that lymphatic capillaries do not actually reach the pulmonary alveoli, but that their distribution ceases at the beginning of the respiratory portion of the ultimate lung structure, the atrium leading into the alveolus. Likewise in the liver, the ultimate functional unit, the lobule, is not supplied with lymphatic capillaries. The fluid leaving the liver sinusoids passes through capillary endothelium and, in the lobule, lies between this endothelium and the liver cells. Lymphatic capillaries are found at the periphery of the lobule, and these carry the highly proteinized liver lymph to collecting trunks which join the thoracic and right lymph ducts. In the spleen, too, lymphatics are observed only in the capsule and the thickest trabeculae. Fluid which filters through the walls of the capillaries and sinuses must permeate the stroma before reaching the lymphatic vessels.

Lymphatic vessels in the kidney appear to begin blindly in two areas (181). The first of these is near Bowman's capsule, and the second is beneath the

mucosa of the papilla. Two networks of lymphatics then arise, accompanying venous and arterial blood vessels of the kidney. Those which originate in the medulla drain upward and outward toward the arcuate vessels, where they join with those beginning near Bowman's capsule draining in the opposite direction. When the junction occurs, larger trunks then drain with the arcuate vessels toward the hilum of the kidney. They may be seen around the renal artery. There do not seem to be any demonstrable lymphatic channels in the glomeruli or about the afferent and efferent arterioles.

The lymphatic drainage of the eye has only recently been clarified (165). The explanation of the almost zero concentration of proteins in the anterior chamber has long been a major problem since no lymphatic drainage had previously been described. Papamiliades, in an anatomical study of lymphatics at the iridocorneal angle of the eye, described lymphatic pathways in the neighborhood of the canal of Schlemm (possibly connecting with the canal) adequate to allow continual removal of proteins from the anterior chamber.

General Anatomic Arrangement of the Main Trunks

The large lymphatic trunks join the subclavian or jugular veins near their junctions. On the left side, the deep cervical duct, draining the head and neck, the subclavian duct, draining the arm, and the thoracic duct, draining the abdominal viscera and lower extremities, enter the venous system in close association with one another. The left bronchomediastinal trunk, draining the left sides of the thorax, lung, and heart may join the thoracic duct in the neck or open independently into the junction of the left subclavian and internal jugular veins. Sometimes all of the trunks empty into a sinus or dilatation from which the lymph then empties into the vein; at other times, they may form a network before entering the vein or they may all enter the vein close together but independently of one another. On the right side, the right jugular trunk, draining the head and neck, the right subclavian trunk, draining the right upper extremity, and the right bronchomediastinal trunk, draining the right side of the thorax, lung, and heart and part of the convex surface of the liver, empty into the right lymphatic duct which, in turn, ends in the right subclavian vein at its angle of junction with the right internal jugular vein. As on the left side, the

three collecting ducts not infrequently enter the vein separately at the junction of the two veins.

The thoracic duct is somewhat more complex than other lymphatic vessels. It usually begins in front of the body of the second lumbar vertebra, to the right of and behind the aorta, by a dilatation of the cysterna chyli. It enters the thorax through the aortic hiatus and ascends through the posterior mediastinum between the aorta and azygos vein. Somewhere between the fourth and sixth vertebral level it inclines to the left, enters the superior mediastinum, passes behind the arch of the aorta and thoracic portion of the left subclavian artery into the neck where, after passing in front of the left common carotid artery, vagus nerve, and jugular vein, it ends, as previously noted, by emptying into the angle of junction of the left subclavian vein and left internal jugular vein. The thoracic duct is the largest lymph vessel and is composed of an endothelial layer, a distinct subendothelial layer of elastic fibers, a media of irregularly arranged but mainly circular smooth muscle cells interspersed with elastic and connective tissue fibers, which is succeeded by the adventitia containing longitudinal and transverse bundles of smooth muscle cells as well as blood vessels and nerves. It contains valves which are quite efficient. Kampmeier (106) found many more valves in the thoracic duct of early embryos than in later stages. In one human fetus, of 4.3 months, he found 42 valves between the jugular confluence and renal arteries. In older fetuses he found as few as three complete valves with numerous vestiges present. Obviously, many of the early valves never progress to the functional stage and some vanish entirely. Kampmeier suggested that the valves which did remain in postnatal life were determined by areas of direct pressure on the duct as, for example, in the area between aorta and esophagus as they cross, an area in which a bolus of food exerts pressure upon the duct.

The above general descriptions are actually subject to more exceptions than have been indicated. Studies of large numbers of animals or species soon demonstrate this variability. McClure & Silvester (134) drew attention to this variability, as far back as 1909, in their report of a study of 25 species involving 50 mammals (primates, carnivora, rodentia, ungulata, and marsupialia). In the adult cat, communication between the lymphatic system and the systemic veins may normally occur on each side of the body, within either one of two or within two typical districts. These two districts include, approximately, the angle of confluence formed by the union of the external

and internal jugular veins (common jugular angle) and the angle of confluence formed by the union of the external jugular and subclavian veins (jugulo-subclavian angle). In the adult cat, neither one of these two districts predominates as the place of communication between the lymphatics and the veins; either one of the two, or both, may serve equally in this capacity. Their studies in other mammals showed that these two districts were the predominant sites of communication between lymphatics and veins, but there was a marked variability in lymphatic arrangement, more so than in veins, not only in different species but among members of the same species. These variations are presumably due to differences in the establishment of these connections in the embryo.

One factor which has been relatively neglected in recent years has been the possible existence of direct lymphatic communications between veins at points other than the entrance of the main ducts. Silvester (200) injected 89 adult monkeys and studied their lymphatic arrangements. He made the significant observation that "Whenever the mesenteric or inguinal lymphatic nodes of a New World species were injected, the injection mass never passed from the lumbar or intestinal lymphatic trunks into the thoracic duct or into the anterior regions of the body, but passed directly into the postcava into the region of the renal veins. A more detailed examination of the vessels in this region of the body revealed the fact that the lymphatics of the digestive organs and of the posterior extremities invariably enter the venous system at the level of the renal veins." Silvester found the posterior communications between the lymphatic and the venous system to vary from two to nine in number and to open at almost any point on the renal segment of the postcava and its immediate tributaries. He examined 16 different species of Old World monkeys and found no evidence of these communications.

It would be of great interest to know if similar communications exist in the dog, rat, and man, animals most frequently used in studies of the lymphatic system. Their existence might modify interpretations based on the supposition that all lymph from the viscera and posterior extremities finds its way back to the blood stream only via the main lymphatic channels.

CONTRACTILITY OF LYMPHATICS

In lower animals, as in the frog, lymph hearts serve to actively propel lymph and distribute it to

various parts of the organism. In the mammal, there are no lymph hearts and lymph is moved along the vessel wherever and whenever the vessel is compressed, a situation analogous to that obtaining with veins and venous flow. The presence of smooth muscle fibers in the walls of at least the larger vessels, and nerve fibers running to them, raises the question as to whether lymphatic vessels have contractility or show vasomotion. Of particular interest are their responses to sympathetic and parasympathetic stimulation and to the chemical mediators, epinephrine and acetylcholine.

Spontaneous contraction of lymph vessels was described as far back as 1774 by Hewson (99), who reported briefly of having seen actively contracting lacteals in horses and dogs killed immediately after the ingestion of food. Since then, many observers have also reported spontaneous contraction of these and other lymph vessels, but there seem to be species differences (159, 160, 175, 202, 224). Definite spontaneous contractions have been observed in the peripheral lymphatic vessels of the bat, rat, and guinea pig. No spontaneous contractions have been demonstrated in the cat, dog, rabbit, and squirrel. The results on mice have been equivocal. The few casual observations in man have shown none. The rate of contraction appears to be directly proportional to the rate of formation of lymph and the contractions are apparently initiated by an increase in intraluminal pressure. They are not dependent on neural control (225). The vasomotion in these vessels seems to be similar to that seen in blood vessels and possibly related to it. Baez and his co-workers (9) observed mesenteric lymphatics during experimental hemorrhagic shock in rats and reported that the lymphatics undergo pronounced compensatory and decompensatory adjustments recalling those seen in metarterioles and precapillaries of the same region. During the period when the animal is recoverable by transfusion, the lymphatic vessels exhibit progressive enhancement of spontaneous motion and of sensitivity to topically applied epinephrine. Reversal of these features occurs upon the prolongation of drastic hypotension. Lymph vessel adjustments after sublethal drum trauma are of a compensatory type, compatible with survival, whereas following lethal trauma, the lymphatics invariably appear atonically distended and resemble those seen in irreversible shock.

Experiments with drugs and faradic and other types of stimulation have also given equivocal results, due probably to differences in experimental procedures, in species, and in a failure to distinguish be-

tween effects on rhythmicity and on caliber of the vessels. There is a suggestion that the response of different lymph vessels may not be uniform. Thus the usual response to sympathetic stimulation or epinephrine administration, in general, appears to be a constriction (175, 187-189, 202), whereas the thoracic duct is dilated by the same procedures (1). Much more careful work needs to be done in this area.

EXCHANGE OF SUBSTANCES BETWEEN PLASMA AND LYMPH

Much evidence has accumulated during the last decade regarding the exchange of substances between plasma and lymph. As discussed previously, the availability of isotopes has made possible quantitative studies of the disappearance of labeled substances from plasma and their subsequent appearance in lymph. The availability of polyethylene tubing has facilitated the collection of lymph and, with a few exceptions, it has been collected from all areas of the body and its contents more or less completely characterized. Beginnings have been made in the study of human lymph (97, 98, 125, 192) under a variety of experimental conditions. The latter studies have been concerned with thoracic duct lymph because of the greater ease of its collection, but will unquestionably be extended in the near future to the investigation of lymph from other areas.

Concepts of capillary permeability and factors which influence it are discussed in detail in Chapter 29. Two concepts have influenced contemporary thinking in the problem of interchange of substances between plasma and lymph, 1) the familiar "Starling hypothesis," and 2) the "pore" concept of capillary permeability.

Starling maintained that the direction and rate of fluid transfer was proportional to the algebraic sum of the effective hydrostatic pressure in the blood capillaries and the osmotic pressure of the plasma proteins. While the capillary membrane was freely permeable to crystalloids, it did not allow larger protein molecules to diffuse readily. The evidence in general confirmation of Starling's hypothesis has recently been reviewed by Yoffey & Courtice (234).

Although Starling conceived the capillary membrane as being only relatively impermeable to protein, there developed a point of view implied or stated in textbooks that capillaries were impermeable to protein if they were healthy and that proteins leaked only when the permeability was abnormal. As will

be discussed in detail below, there is now no question but that "normal," "healthy" capillaries leak protein (and other macromolecules) and that the protein content of lymph collected from different areas of the body is primarily an expression of the leakage of these macromolecules from the blood stream. Thus, during the course of a day, 50 per cent or more of the total circulating protein escapes from the blood stream and is returned to it via the lymphatic system.

An additional factor in the reluctance to the acceptance of the idea that lymph was primarily derived from capillary filtrate was literal adherence to the pore concept of capillary permeability. It was difficult to reconcile the appearance of proteins and other macromolecules in lymph with the size of the "pores" postulated for capillary membranes (118). It is now obvious that the pore concept as originally reviewed by Pappenheimer (166) must be modified and reconciled with the more recent work on lymph to permit of the possible operation of active processes (141).

Drinker and his colleagues elaborated on Starling's concept of capillary permeability. As a result of analysis of lymph from different areas of the body they concluded "that the capillaries practically universally leak protein; that this protein does not reenter the blood vessels unless delivered by the lymphatic system; that the filtrate from the blood capillaries to the tissue spaces contains water, salts, and sugars in concentrations found in blood, together with serum globulin, serum albumin, and fibrinogen in low concentrations, lower probably than that of tissue fluid or lymph; that water and salts are reabsorbed by blood vessels and protein enters the lymphatics together with water and salts in the concentrations existing in the tissue fluid at the moment of lymphatic entrance" (61). During the last decade, as will be discussed below, experiments particularly with isotope-labeled proteins and other macromolecules have confirmed the point of view of the Drinker group and have shown unequivocally that "healthy" capillaries leak plasma protein and other macromolecules and that these are returned to the blood stream via the lymphatics. To date, all plasma proteins have been shown to be present in lymph from all areas studied (234).

Extravascular Pool and Circulation of Protein

When a labeled protein is injected intravenously, the specific activity (ratio of concentrations of labeled

and natural protein) of lymph gradually rises (44, 116, 149) until it reaches that of plasma in 7 to 13 hours in the case of the thoracic duct (220). Samples of lymph and plasma analyzed after this time show that the specific activities in the two compartments remain equal and decline at the same slow rate. This early growth type of curve suggests that protein leaves the blood stream and mixes with the extravascular protein pool before being taken up by the lymph ducts. If lymph were a direct product of plasma, the experiments should yield a "decay" type of curve. This point of view is strengthened by experiments in which large infusions were given to dogs (116, 221). Infusions roughly equivalent to or greater than plasma volume resulted in increased flow of thoracic duct lymph and albumin leakage increased significantly (fig. 1). It was obvious that the eventual level of total circulating plasma protein was determined by a number of factors. Infusion results in the filtration of a more dilute protein solution than that filtered before the infusion, but one which has a relatively greater albumin content as well as a larger volume. This then mixes with the relatively more concentrated preinfusion interstitial fluid so that the concentration of albumin in lymph after the infusion is intermediate between that of the interstitial fluid formed before the infusion and the newly formed interstitial fluid. The eventual effect of an infusion on the total plasma protein level will thus depend upon *a*) the degree of distention of the interstitial space as a result of the infusion, since a greatly distended interstitial space may hold much of the protein which ordinarily might have gone back to the circulation via the lymphatics; *b*) the rate (and amount) of albumin leaving the capillaries; *c*) the amount of albumin present in interstitial fluid available for mixing with the plasma filtrate; and *d*) the rate of lymph flow. If the lymph does not return to the venous system or if the amount disappearing from the plasma is greater than the amount returning via lymph, plasma albumin will be decreased and remain low until the usual conditions of flow are re-established. These results with isotopically labeled albumin emphasize that we are not concerned with mobilization of cell protein, as has been suggested in the literature (4, 59), but primarily with the movement of interstitial fluid protein. Addition of new protein from any source drained by lymph coming to the thoracic duct would have been apparent by a lowering of specific activity. This was never seen.

Evidence for the existence of an extravascular albumin mass as a separate entity and in equilibrium

FIG. 1. *A*: Ratio of lymph volume flow (ml/min) after the start of the infusion to the preinfusion (control) lymph volume flow plotted against the time after the beginning of the infusion. The 250-ml infusions lasted approximately 8 min, the 500-ml infusions lasted 15 min, the 1000-ml infusions lasted 30 min, and the 2000-ml infusions lasted approximately 1 hour. Average control lymph flow for these experiments is 0.5 ml/min. *B*: Ratio of albumin flow (ml/min) after the start of the infusion to the preinfusion (control) lymph albumin flow plotted against time after the beginning of the same experiments as in *A*. Numerals to the right of the infusion volumes are the numbers of experiments which were averaged in each group. Average control albumin flow for these experiments is 8.5 mg/min.

with the intravascular mass was obtained from experiments on unanesthetized, healthy greyhounds, infused with 25 per cent albumin or bled, into which we injected I^{131} -labeled albumin and then determined the albumin specific activities (218). We showed that albumin specific activity curves can be altered by changing the ratio of intravascular to extravascular albumin masses in a manner predicted by a two-compartment system. Increase of intravascular mass (by infusion) relative to extravascular mass results in a smaller initial disappearance of albumin specific activity from the blood stream and a faster approach to equilibrium. Decrease of intravascular albumin mass relative to extravascular mass by bleeding shows that 50 per cent of albumin replacement after hemorrhage appears to be accomplished within 24 hours. Almost all this protein comes from the extravascular compartment. Rapid anabolism accounts for the replenishment of protein for the next 2 to 5 days, during and after which there is a reduced catabolism of the existing plasma albumin. Thus there are net movements from the extravascular mass into plasma when the equilibrium between intravascular and extravascular masses is disturbed.

Benson *et al.* (14) concluded that under standardized resting conditions a given tissue eliminates a nearly constant amount of protein in its lymph per unit of time and that the protein concentration in the lymph from the intestine or liver of the rat varies inversely with the volume of lymph flow. The concentrations of protein fractions in rabbit lymphs, and the rates of exchange of radioiodinated human serum

albumin between plasma and lymph which they observed, suggested that the equilibration of plasma proteins with lymph is rapid in the liver, intermediate in the intestine, and slow in skeletal muscles. These findings are consistent with our recent demonstration (see figs. 2 and 3) of differences in blood capillary permeability in different areas to macromolecules (141) and the suggestion that there are several sets of capillary pores of different sizes, large pores predominating in the liver, small pores in muscles, and both size pores in the intestinal capillaries. Alternately, the suggestion was made that cytopempsis or a similar process may be involved.

LYMPHATIC RETURN AND BLOOD VOLUME REGULATION

Lymph not only returns protein and other macromolecules from the extravascular to the vascular system but also drains fluid representing the excess of filtration over reabsorption through the capillary wall. As discussed later, the amount of lymph returned to the blood stream via the thoracic duct alone per 24 hours is roughly equivalent to the plasma volume. It is thus obvious that the return of lymph plays an essential role in the maintenance of the blood volume level. However, little definitive data is available on this point. Courtois *et al.* (50) state that in unpublished experiments on dogs anesthetized with Nembutal "the rate of escape of fluid and protein in lymph was equivalent to a daily loss of 60 per cent

FIG. 2. Typical experiment in anesthetized dog showing disappearance of dextran of average molecular weight of 35,000 from plasma and its appearance in lymph of various areas.

FIG. 3. Same experiment as in fig. 2 showing disappearance of radioactive albumin from plasma and its appearance in lymph of various areas.

of the plasma and 45 per cent of the circulating plasma proteins." We have confirmed these observations (Magruder, Kern, and Mayerson, unpublished). In 20 dogs, drainage of thoracic duct lymph for 8 hours resulted in an average drop of 16 per cent in plasma volume. CoTui and his colleagues (46, 196) found that when they bled dogs whose thoracic ducts were ligated there was a greater drop in the hematocrit level than in dogs bled but with intact lymphatic circulation. This hemodilution lasted at least 8 days after hemorrhage in the duct-ligated animals but

disappeared in about 48 hours in nonduct-ligated animals.

Another aspect of the problem is the well-known lymphagogue effect of infusions. As infusions are made larger, lymph flow increases proportionately so that with large infusions in dogs (2000 ml) the thoracic duct lymph flow may reach a peak value of about 14 times that of the preinfusion value (221). The displacement of fluid from the circulation supplements the diuresis through the kidneys and may be considered as a fine adjustment of the blood volume

so that not all of the fluid is irrevocably lost from the body. Large infusions also increase protein leakage but here again the protein is slowly returned to the blood stream and minimizes changes in total circulating protein and loss of its oncotic effect.

It should, perhaps, be emphasized that blood is the chief source of the water of lymph. Benson *et al.* (15) measured the content of either D₂O or Na²⁴ in intestinal lymph, portal venous blood, and femoral arterial blood of anesthetized hydrated rats after administration of the isotope into the stomach, duodenum, or peripheral or portal vein. Little, if any, water or sodium found its way into lymph after absorption from the small intestine. At least 99 per cent appeared to be carried in portal venous blood. The amount of isotope found in intestinal lymph was proportional to lymph volume whatever the route of administration. Thus, even during absorption of water or sodium ion from the small intestine, blood is the principal source of the water and sodium in lymph.

TRANSPORT FUNCTION

Lipids

There has been considerable interest, particularly during the last decade, in the transport of lipids—the physical state in which they are carried in the blood and their exchange between blood plasma and tissue cells. The availability of isotopes has facilitated the design of experiments concerned with lipid transport by lymph. It is now apparent that the lymphatic system plays an important role in lipid transport as it does in protein transport. This may be because the passage of plasma lipids through the capillary membrane depends on lipid-protein complexes rather than on the physical properties of the lipids themselves.

All the different lipid-protein associations present in the plasma have been identified in thoracic duct lymph (162), as well as in cervical and leg lymph (49). In the dog and cat, alpha-lipoprotein predominates. When rabbits are fed cholesterol, however, the plasma beta-lipoprotein may increase considerably with a much smaller rise in alpha-lipoprotein. Under these circumstances lymph contains beta-lipoprotein. The evidence suggests that beta-lipoprotein leaves the blood circulation at a slower rate than does alpha-lipoprotein. Not only do alpha- and beta-lipoproteins appear in the lymph in the postabsorptive state, but lymph from the cervical, hepatic, and leg

ducts—all draining tissues remote from the alimentary tract—also contains chylomicrons (49). As Yoffey & Courtice (234) state: “We can readily understand how the intestinal lymph always contains chylomicrons even in what we call the postabsorptive state. The presence of chylomicrons in lymph from other tissues, however, suggests that they come either from the blood stream by passing through the capillary membrane or from the fat depots. The evidence indicates that the chylomicron count in the lymph may vary with that in the blood, which suggests that these particles may pass through the capillary membrane and so appear in the lymph. For example, the hepatic and cervical lymph ducts were cannulated in a fat-fed cat and chylomicron counts made on lymph and plasma. The thoracic duct which was pouring very fatty chyle into the blood stream was then cannulated and the lymph collected. The chylomicron count in the plasma fell in the next few hours and with this fall the counts in the hepatic and cervical lymph also fell. The fatty chyle which had meantime been collected from the thoracic duct was then injected intravenously making the plasma quite milky. The chylomicron counts in the hepatic and cervical lymph subsequently rose.” Geyer *et al.* (83) attempted to assess the permeability of capillaries to serum cholesterol in humans by measuring the disappearance of cholesterol from the blood in the forearm during various degrees of venous congestion. Under these circumstances, measurable amounts of cholesterol were filtered and were related to the rate of fluid filtration and the initial level of the serum cholesterol. The results were similar to those of Landis *et al.* (119) for serum proteins. It may also be of interest to mention that the rise of plasma cholesterol occurring in the hypothyroid state does not appear to be due to any decrease in its ability to diffuse out of the plasma (79). Electron microscope studies suggest that chylomicrons can be transferred directly across cell membranes (5, 164) by the active process of pinocytosis. The probability that some active process is concerned in the transfer of macromolecules from the capillaries to lymph is discussed elsewhere (141).

When fatty chyle or artificial fat emulsions are injected into the blood stream, they leave the circulation very rapidly, but the amounts found in lymph are relatively small (140, 142, 148, 151, 233). The latter investigators injected fatty chyle collected from fat-fed cats into postabsorptive cats and determined the lipid disappearance from plasma and its appearance in hepatic, intestinal, and cervical lymph.

These calculations showed that protein left the circulation at the rate of 77, 142, and 11 mg per hour in the liver, intestine, and cervical tissues, respectively, or a total leakage of 230 mg. In another cat, 2540 mg of injected fat left the circulation within 2 hours during which time the leakage of protein was 448 mg. It is obvious that fat in chylomicron form can disappear from the blood stream much faster than protein. The chylomicron fraction of lymph appears to carry neutral fat (233).

Reinhardt *et al.* (182) injected biosynthesized P^{32} -labeled phospholipid into a peripheral vein of rats with thoracic duct fistula and reported that 9 to 20 per cent of the injected phospholipid could be recovered in the thoracic duct lymph in the succeeding 3 to 6 hours. McCandless & Zilversmit (131) obtained labeled lymph by feeding dogs with I^{131} -labeled triolein. The labeled lymph was administered to recipient dogs, and the rate of disappearance of the lymph lipids from plasma was followed. Lymph I^{131} triglycerides were found to disappear from the circulation rapidly, with an initial half-time of several minutes. Disappearance of I^{131} phospholipids was slower as determined in the same animals, 10 to 40 per cent of the injected dose remaining in the blood 1 to 2 hours after injection. These results were similar to those previously obtained by the same authors using artificially prepared fat emulsions (130).

The presence or absence of bile appears to influence the pattern of absorption and lymph transport of dietary soaps and triglycerides in the dog. Rampone & Sigurdson (179) recently reported that the absorption of triolein and sodium oleate was significantly diminished in the absence of bile. In the normal dog, 90 per cent of fed triolein and 94 per cent of fed sodium oleate were recovered from the thoracic duct as lymph lipid. In dogs with bile fistula only 8 per cent of fed triolein was recovered in lymph compared to 40 per cent of sodium oleate.

The route of absorption of steroids from the gastrointestinal tract seems to be determined largely by the chemical nature of the compounds. Methyl testosterone, 17α -methyltestosterone and cortisone- $4-C^{14}$ acetate are absorbed in the rat by way of the portal circulation (23, 24, 102). Studies in human subjects have shown that testosterone, cortisone, and cortisone acetate are also absorbed in this manner and are virtually absent from lymph (97). In contrast, absorption of cholesterol into lymph of the rat (17, 41) and dog (152) accounts for essentially all the sterol that enters these species from the diet. This is also true for man (98). Data from the different species

studied is consistent in showing that much of the cholesterol is esterified by the intestinal mucosa (25, 41, 98, 213). A number of factors appear to influence the lipid composition of lymph during cholesterol absorption (212). In rats given intragastrically emulsions containing cholesterol, oleic acid, and sodium taurocholate, addition of albumin resulted in a rapid increase in total lymph lipid which was much more marked than in those animals not receiving albumin. The amount of lymph cholesterol, however, was less for a 24-hour period. The presence of taurocholate and oleic acid in administered emulsions resulted in elevation of ester cholesterol, indicating increased absorption of endogenous cholesterol (211). Addition of cholesterol to the emulsions also resulted in further significant increase in the ester cholesterol fraction in thoracic duct lymph. In further studies (207), it was shown that small doses of fed cholesterol- $4-C^{14}$ lead to labeling of cholesterol fractions of mucosa and lymph without an increase in the level or turnover in lymph. Feeding tracer dose with oleic acid and sodium taurocholate increases the turnover rate of the pool which leads to an increased amount of labeled and unlabeled cholesterol in lymph. In fasting rats, the major fatty acids in lymph are palmitic, linoleic, and oleic acids with polyunsaturated fatty acids comprising 36 per cent of the total cholesterol fatty acids (206). After feeding oleic acid only 42.3 per cent of the total was present as oleic acid. The total cholesterol fatty acid composition of lymph is evidently determined not only by dietary fatty acid, but by the composition of the fatty acid pool in the mucosa from which fatty acids are drawn for esterification of cholesterol, a suggestion which had been made earlier by previous workers (30).

Bloom *et al.* (22) fed unanesthetized rats C^{14} -labeled stearic and myristic acids and found that nearly all the absorbed C^{14} was recovered in intestinal lymph. This finding, taken in conjunction with earlier work with labeled palmitic and pentadecanoic acids, showed that lymph is the major if not the exclusive agent for the transport of absorbed long-chain fatty acids. On the other hand, when similar experiments were carried out with labeled lauric acid and decanoic acid, recoveries of the absorbed C^{14} amounted to 15 to 55 and 5 to 19 per cent, respectively. Since it was shown that the findings were not the result of bacterial action, it would appear that the major portion of a short-chain fatty acid is transported via the blood stream from its site of absorption. Blomstrand *et al.* (21) have extended this type of study to man. They

found that linoleic acid-1-C¹⁴ incorporated in dietary triglycerides, or fed as free acid, becomes esterified with the same classes of lipids in human thoracic duct lymph as oleic and palmitic acid. Evidently, digestion and absorption of these fatty acids are comparable, as well as their transfer into intestinal mucosa and resynthesis in lymph lipids. This is in confirmation of work on animals by the same group. They also confirmed earlier findings on animals that stearic acid-1-C¹⁴ was found in a higher percentage incorporated in lymph phospholipids than was found for linoleic acid and for palmitic and oleic acids. After isolation of lymph lecithins, there was a difference in the position of the label in lecithins of lymph according to the fatty acid used. After feeding linoleic acid-1-C¹⁴, approximately 75 per cent of the label in lymph lecithins was localized in the alpha-position. With stearic acid-1-C¹⁴, however, about 80 per cent of the label was found in the beta-positions. Their evidence indicates that there is a distinct manner in which stearic acid-1-C¹⁴ and linoleic acid-1-C¹⁴ are incorporated into thoracic duct lymph lecithins, reflecting probable differences in their metabolism.

Rampone (178) recently reported experiments in which he measured phospholipids of lymph in relation to the total lipid in 16 dogs with chronic thoracic duct fistula during the postabsorptive state and following the administration of various lipid types (triolein, soya lecithin, oleic acid, etc.) in the diet. He found that phospholipid transport related linearly to total lipid transport under all conditions studied, including the postabsorptive state. The percentage of lymph lipid transported as phospholipid ranged from 3 to 18 per cent and was independent of the type of lipid fed. Depriving the animals of phospholipid precursors in the diet for as long as 90 days previously failed to alter this relationship or the total quantity of lipid transported. Since the phospholipids increased linearly with the total lipid under all conditions studied, Rampone believes it likely that the phospholipids associate with the absorbed lipid in some manner which relates to lipid transport, possibly serving in the capacity of chylomicron emulsion stabilizers during the transport phase. He points out that while the plasma may be the source of the phospholipids, the rate of filtration from plasma to lymph would be somehow dependent on the lipid concentration in lymph, since the phospholipids of lymph increased in proportion to the total lymph. Previous work by Bollman *et al.* (26) suggests that the mucosa of the small intestine may normally be

the source of phospholipids for plasma during fat absorption.

An interesting application of the study of lymph and its possible role in the pathogenesis of atherosclerosis was reported by Kellnor (111). He collected leg lymph from rabbits rendered hyperlipemic by cholesterol feeding, by the injection of the surface-active agent Triton A-20, and by the injection of alloxan. He found (as have others) that leg lymph contained protein in a concentration equal to one-third to one-half that of the blood serum. Electrophoretic analyses showed a pattern similar to that of serum. The total lipid concentration was also about one-third to one-half that of blood serum and the major lipid fractions, cholesterol and phospholipid, were present in lymph in about the same relationship. In the cholesterol-fed rabbits, the leg lymph showed a striking increase in lipids as did the serum. On the basis of his results he concluded that: "It seems likely that under normal conditions there is a constant flow of fluid containing various serum lipids and proteins across the endothelium into the walls of blood vessels; this material normally passes through the wall and is completely removed by way of vasa vasorum and lymphatics. In certain conditions, however, where there are increased amounts of lipid in the blood, or where there are excessive quantities of certain types of lipids (beta-lipoproteins of the S_f 12-20 molecules of Gofman), the removal of these particles from the wall of the vessel is incomplete and some remain behind to initiate the process of atherosclerosis. In hypertension, the increased hydrostatic pressure appears to cause an increase in the quantity of serum lipoprotein that diffuses across the vessel wall, thereby increasing the possibility for incomplete removal and hence for deposition of lipids. In those areas of the vascular tree where the removal mechanism has been altered, as for example in syphilitic aortitis or in experimentally produced trauma to the vessel wall, the free transport of lipid and other particles across the vessel wall is impeded, and in these areas the lipid is therefore more apt to precipitate and to give rise to atherosclerosis. In this theoretical formulation of the pathogenesis of atherosclerosis, the artery wall is regarded as an organ which is constantly bathed by a serum transudate containing, among other things, various serum lipoproteins, most of which pass on through, some of which doubtless are metabolized locally, and a few of which remain behind to cause mischief. Atherosclerosis, broadly considered, may thus result either from qualitative or quantitative changes in the serum lipoproteins

that filter constantly across the walls of blood vessels, or from local structural changes inherent in the vessel wall, or the result of age or disease, that serve to hamper the normal passage of these fatty substances."

Enzymes

Many enzymes are found in lymph in small concentrations (234). Their concentrations are usually higher in intestinal and liver lymph than in cervical or leg lymph, but are usually lower than in plasma and run parallel with the concentration of proteins (18, 28). It is probable that, in most instances, these substances have leaked from the blood stream and take part in the extravascular circulation via the lymphatics.

On the other hand, certain enzymes seem to be transported to the blood stream from their cells of origin via the lymph. Flock & Bollman (74) made an interesting comparison between the activity of rat intestinal lymph with respect to amylase and tributyrinase. The activities of the two enzymes in intestinal lymph are generally less than in plasma. The 24-hour secretion of amylase in lymph is greater in fed than in fasting rats, but much of the increase is due to the increase in lymph volume. External drainage of lymph for 2 days does not significantly alter the plasma amylase level. On the other hand, although the 24-hour secretion in lymph of tributyrinase is also much greater in fed than in fasting rats, it appears to represent a specific effect of ingested fat on the chemical composition of intestinal lymph. External drainage of the lymph markedly decreases the tributyrinase content of plasma. These results are similar to those previously obtained by the same authors with respect to alkaline phosphatase (72). The increase of alkaline phosphatase of intestinal lymph following the feeding of fat is abolished or greatly diminished when the bile duct is ligated or the bile drained away in a biliary fistula (73). The presence of bile thus seems to be essential for the release of alkaline phosphatase from the intestinal mucosa.

The histaminase activity of lymph has received considerable attention from Carlsten and his colleagues. They were led to these studies by their failure to demonstrate the presence of histamine in venous blood during reactive hyperemia and muscular tetanus, where histamine was alleged by some investigators to be liberated. They then turned to lymph on the grounds that lymph is closer to the tissue cells which are thought to liberate histamine, and

therefore histamine should accumulate in greater concentration in lymph than in plasma. They used dogs, anesthetized with Nembutal, and collected lymph from the thoracic duct (37). Lymph had no histamine in detectable amounts. In contrast to guinea pigs, rats, and rabbits, dogs show low plasma histamine activity. The plasma histamine concentration could be raised to very high levels by histamine infusion or by intravenous injection of histamine liberators (curare and trypsin) without the appearance of detectable amounts of histamine. Study of the histaminolytic activity of the lymph showed it to be more than 30 times as powerful as in plasma when tested *in vitro*. *In vivo*, intralymphatically administered histamine was inactivated at a very high rate. This same group has also used cats and have described a simple micromethod for estimation of the small amounts found in lymph and plasma (38, 231), and showed that the histaminolytic activity of lymph is not changed by routine procedures such as anesthesia, laparotomy, gentle handling of the viscera, or by reactive hyperemia or pregnancy (35, 232). Adrenalectomy is followed by a marked increase in histaminase content of thoracic duct lymph (but not in plasma) which reaches a maximum within 2 hours and persists approximately 24 hours (36). Infusion of an adrenocortical extract will reverse this increased activity (39). The histaminolytic activity of cervical and leg lymph is less than that of the thoracic duct and seems to originate from the kidneys and gut (34).

It has been suggested that the lymphatic transport of lipase may be concerned with the changes seen in disseminated pancreatic fat necrosis (171). So-called pancreatic and peripancreatic fat necrosis is supposedly due to the splitting of neutral fat into glycerol and free fatty acid by pancreatic lipase which has escaped from the injured pancreas. The free fatty acids are thought to combine subsequently with calcium in the tissue and tissue fluids to form insoluble calcium soaps which give rise to the opaque white areas seen in the fat depots of the abdominal cavity and elsewhere. Perry made intraperitoneal injections of a mixture of pancreatin and graphite suspension in rats and at necropsy found multiple areas of fat necrosis in the abdominal and thoracic cavities, closely associated with graphite-delineated lymph channels. The evidence of the participation of the lymphatics in this disease is quite suggestive and indicates the desirability of further investigation of the role of lymphatics in this and other diseases.

Reizenstein *et al.* (183) recently reported experi-

ments on two beagles to which they gave $\text{CO}^{58}\text{-B}_{12}$ by stomach tube and measured its absorption and distribution between thoracic duct lymph and plasma. They found only a very small amount of the total dose in lymph which they believe to have leaked from the plasma. They interpret their results as suggestive that vitamin B_{12} is absorbed directly into the blood stream as a compound with a molecular weight only slightly higher than that of pure crystalline B_{12} . If it were absorbed as the entire intrinsic-factor-molecule (mol wt $\pm 70,000$) more should have been found in the lymph, since this large molecule probably cannot easily get into the plasma.

Coagulation Principles

Lymph from all parts of the body clots, but does so less readily than plasma. The concentrations of fibrinogen and of prothrombin in lymph are always less than in plasma and vary considerably in different regions just as concentrations of other proteins vary. Mann *et al.* (139) drained intestinal lymph from rats and found that marked hypoprothrombinemia developed rapidly, usually within 24 hours. If adequate amounts of vitamin K were administered parenterally, a normal level of prothrombin was maintained, despite loss of lymph. Transfusion of twice the animal's normal volume of plasma did not maintain a normal value for prothrombin while lymph was lost. Under the conditions of their experiments, it appeared that vitamin K was absorbed practically exclusively through the lymph and very little of it was stored, whereas the turnover of prothrombin was extremely rapid.

The concentration of fibrinogen of canine thoracic duct lymph is about 50 per cent that of plasma (29, 70). Brinkhous & Walker (29) found that the mean prothrombin level, expressed as a percentage of that in the plasma, was 93.2, 51.2, and 7.6 for hepatic, thoracic duct, and leg lymph, respectively. These findings are consistent with the known differences in permeability of capillaries to macromolecules in the leg and liver. Infusion of heparin into anesthetized dogs (214) prolonged thrombin and prothrombin times of plasma immediately, but the effect was delayed in thoracic duct lymph and required larger doses for its production. The differences between plasma and lymph were more marked with cervical lymph, which again may reflect the differences in permeability between the capillaries in the areas drained by the cervical and thoracic ducts.

Langdell *et al.* (120) have extended and, in general, confirmed these observations. They also found that lymph samples are not fully active at the time of collection. On exposure to glass surfaces in the presence of anticoagulant, the clotting time becomes shorter during the first 20 to 40 min. Coagulating lymph has a high residual prothrombin even after 18 to 24 hours in glass containers. Thoracic duct lymph contains sufficient thromboplastic materials so that adequate amounts of thrombin can form to produce a fibrin clot, but it does not contain the thromboplastic materials required for complete prothrombin utilization. These authors conclude "thoracic duct lymph in this respect might be compared with platelet-poor native plasma; however, the initial phase of relatively rapid prothrombin utilization in clotting lymph is unlike the slower initial utilization reported to occur in platelet-deficient plasma systems. The nature of the thromboplastic material in lymph is not known, but it would appear that the lipid materials being transported could furnish clot-accelerating activity. Additional studies are needed to evaluate the role of the lipid materials in the coagulation of lymph. Such studies promise to furnish considerable information on the role of alimentary lipemia on blood coagulation since lymph drains directly into the venous circulation."

Iron

The demonstration of iron within leukocytes of the intestinal villi, subsequent to the oral administration of iron, led Macallum, in 1894, to suggest that leukocytes are partially responsible for the transfer of iron from the intestine (133). Since then, other investigators (81, 84) demonstrated an increase of iron within mesenteric lymphatics after oral iron administration and suggested that lymphatics are involved in iron absorption and transport. Histochemical studies indicated that phagocytes might be concerned in mediating the transfer of iron from the intestine into the lymphatics (84), but more recent evidence does not support these concepts. Thus, Moore *et al.* (147) showed that iron absorbed from the intestine of dogs passes directly into the blood stream and only a minimal amount appears within the intestinal lymphatics. Endicott *et al.* (68) showed that the iron demonstrable in intestinal lymph of dogs and guinea pigs was derived from sources other than a single test meal. They showed that in the dog iron was transported chiefly via the portal vein with

only an insignificant amount appearing in thoracic duct lymph. Similar conclusions were reached by Reizenstein *et al.* (183). Koler & Mann (115) found that the iron content of intestinal lymph of cats maintained on a normal diet was relatively constant over periods as long as 7 days. At lymph outputs of 1 ml per hour, there was an hourly output of 0.5 μ g of iron. Peterson & Mann (174), using radioiron, found that only an insignificant portion of an orally administered amount of radioiron appeared in the lymph of rats with total intestinal-lymph fistulas—less than 0.1 per cent of the total amount of radioiron administered and only 2.0 to 5.0 per cent of the total amount of iron absorbed from the gastrointestinal tract after 8 hours. Everett *et al.* (69) confirmed these results in the rat. The absorption of subcutaneous FeCl_3 occurred primarily via the blood vessels, but subcutaneous plasma-bound iron passed almost exclusively into the lymphatics. Intravenously administered iron appeared rapidly in the lymph. These observations and those of previous workers are unquestionably related to the fact that iron is normally bound to protein in plasma. Since proteins leak slowly from blood capillaries, we would expect to find small quantities of iron-protein compounds in lymph from all areas. Since the capillaries of the intestine are more permeable to protein than those of other areas, and since protein leakage is greatest in the liver, larger amounts would be present in intestinal, hepatic, and thoracic duct lymph. It is also of interest that Everett and co-workers found no evidence that leukocytes played more than a negligible role in iron absorption regardless of the method of iron administration.

Miscellaneous

Scattered reports deal with a variety of substances transported in lymph. Thus Salter (193) reported that the protein-bound iodine per gram of protein in cervical lymph was concentrated relative to the homologous serum value. Klitgaard *et al.* (113, 114) found that about 3 per cent of a subcutaneously administered dose of thyroxine- C^{14} appeared in thoracic-duct lymph in rats during an 8-hour experimental period. The level of radioactivity in lymph was lower than in plasma on a volume basis but significantly higher when calculated on the basis of protein content. Chromatographic analysis of lymph samples showed the radioactivity present to be from unaltered thyroxine. It would be interesting to know

the extent to which other protein-bound hormones are transported in lymph. We can assume that small quantities escape from the capillaries as do other macromolecules and are returned via the lymphatic system.

Dietrich & Siegel (53) recently reported an interesting study designed to determine whether nucleotides or nucleotide precursors synthesized in an organ or tissue, e.g. liver, were available to nourish other tissues and organs. The stimulus for their studies arose from observations that certain cell types cannot utilize free bases and must secure the nucleoside containing the base from an external source, apparently other cell types. They argued that if bases and other nucleotide precursors are secreted by a distant organ or cell type, these compounds may be present in both the blood and lymph which bathes the cell or organ. Blood, however, contains such a mass of living cells that it is difficult to determine whether intermediates found in the plasma are derived from the cells within the blood or from other somatic cells nourished by and yielding their products to the blood. Since the cell population in lymph is insignificant when compared with that of blood, it might be assumed that metabolites found in the lymph would reflect more closely the metabolism of the tissue through which it has passed than that of the lymphocytes. Working on rats anesthetized with Nembutal, they injected glycine-2- C^{14} and nicotinamide-7- C^{14} and found adenine, guanine, cytosine, uracil, and uric acid in measurable amounts in thoracic duct lymph. No detectable quantities of nucleosides were observed. The quantity of acid-soluble nucleotides found was equivalent to that which would be expected from the lymphocytes present in the lymph samples analyzed. Lymph collected for a 45-hour period following the injection of carbon-labeled glycine contained no significant amount of labeled purine derivatives. At the end of this period, however, liver tissue still contained appreciable quantities of labeled acid-soluble nucleotides. Lymph collected for a similar period of time after the injection of carbon-labeled nicotinamide contained very small amounts of radioactivity. While the results raised many unexplainable questions and suggested the need of further work, they did confirm previous investigations of plasma in indicating that if these compounds are essential for the proper nutrition of certain cell types, these purine derivatives are not transported from sites of synthesis, such as the liver, via the lymphatic ducts.

SIGNIFICANCE OF SOME REGIONAL LYMPHATICS

Thoracic Duct

The size, high rate of flow and accessibility for cannulation have made the thoracic duct the duct of choice in studies on lymph. A considerable amount of data has therefore accumulated during the last 125 years relative to its characteristics under a variety of conditions in many species, including man (50, 51). During the last decade, as previously indicated, the advent of polyethylene tubing made possible chronic experiments in which the cannulas could be left in place and the data collected in the unanesthetized animal and man and in a reasonably "normal" physiological situation.

The thoracic duct receives lymph from the abdominal viscera, the lower part of the trunk, and the lower extremities, and empties it into the jugular vein. The rate of flow in the thoracic duct is greater than the sum total of flow from all other ducts. Yoffey & Courtice (234) have assembled available data on the rates of flow in the dog, cat, rabbit, rat, horse, bull, cow, goat, and man. To this list may be added the data of Shrewsbury on the mouse (198). It is interesting that in spite of the many variables involved in the experimentation (anesthesia, time of feeding, duration of collection, etc.) the thoracic duct lymph flow in all species studied averages about 2 ml per kg per hour in nonruminants and somewhat more in ruminants. If we accept the average figure for plasma volume for most animals of 45 ml per kg, it is obvious that the amount of lymph returned to the blood stream via the thoracic duct per 24 hours is roughly equivalent to the plasma volume. The above calculations are in terms of the quiet, resting animal. Under conditions of activity, the return is considerably greater.

Hepatic Lymph

The contribution of the liver to thoracic duct flow appears to be variable. It may contribute from one-fourth to one-half of the flow in the dog (33) and cat (149, 150), and only about 10 per cent in rats (138). Actually, the anatomy of the hepatic lymphatic drainage is such that direct measurement of total hepatic lymph flow is difficult and the data available have been derived from indirect estimates or from experiments where usually only one large hepatic duct was cannulated. The values obtained by such direct cannulation (0.4–1.2 ml/kg/hour) suggest that liver lymph flow is higher than that of any other part of the body of the dog.

Two hilar lymphatic pathways have been described for the canine liver (184): 1) a main hilar system, draining predominantly the right lobes; and 2) an accessory hilar system, draining mainly the left lobe. Usually all of the hilar lymph seems to pass into one common efferent trunk which then discharges it into the cisterna chyli. About 80 per cent of lymph leaving the canine liver probably travels by the hilar route and the remaining 20 per cent by the hepatic venous lymph route.

Not only is liver lymph flow higher than from anywhere else in the body, but it also has the highest protein concentration, equaling from 80 to 95 per cent of plasma concentration in dogs, rats, and cats (141, 149, 157, 158, 234). Electrophoretic analyses show that protein distribution in hepatic lymph is similar to that in plasma. These data are derived from acute experiments on anesthetized animals, from animals with chronic lymph fistulae, experiments in which T-1824 or other dyes have been used to label proteins, and from isolated liver preparations.

The extraordinarily high permeability of the hepatic endothelia involved in hepatic lymph formation has been demonstrated by the use of dextran fractions of graded molecular weights (92, 141). While the results of these investigations differ in details, they are consistent in showing that high molecular weight dextrans appear in hepatic lymph in greater concentration than in lymph from other areas (fig. 4) and suggest that hepatic lymph represents a plasma filtrate formed in a region of highly permeable capillary walls. In a recent review of hepatic circulation (27) Brauer suggests: "As a working hypothesis compatible with the major part of the available data, one may accept the following: Liver lymph formation involves two sites. The first of these would appear to be the sinusoidal portion of the hepatic vascular tree where a very large area of endothelium with demonstrably large pores surrounds the blood stream, and where one would expect the formation of a large volume of lymph, differing from the blood principally in the absence (in the normal liver, at least) of erythrocytes and of the greater part of the leukocytic elements. This primary lymph for the most part moves countercurrent to the blood stream to enter the lymphatic vessels within the Glisson sheath. Here it passes through the peribiliary plexus, the second site important in liver lymph formation. The principal role of this plexus in the normal liver should be sought in the opportunity it provides for secondary modification of liver lymph composition by exchange of soluble components between bile, lymph, and blood."

The high rate of flow of hepatic lymph coupled

FIG. 4. Curves illustrating relative permeability coefficients for dextrans of different molecular weights. Relative permeability coefficient is ratio of dextran between lymph and plasma divided by ratio of albumin between lymph and plasma. See (141).

with its high protein concentration emphasized the importance of the hepatic lymph system in the turnover of plasma volume and plasma proteins. Little or no new protein, as such, is added to lymph in the liver (234), and the large amount of protein is that which has leaked from blood capillaries and sinusoids. Nix *et al.* (157, 158) estimated that, in the anesthetized dog, the volume of lymph collected from the liver, intestine, and thoracic duct was equivalent in 24 hours to 47, 39, and 95 per cent, respectively, of the estimated plasma volume. They found, as have others, that more than half of the total circulating plasma proteins passes through the thoracic duct daily. When they produced hepatovenous congestion or cirrhosis, the flow of hepatic lymph was two to five times that found in normal dogs. The equivalent of 70 to 207 per cent of the total circulating plasma protein passed through the liver lymphatics in 24 hours. Likewise, Friedman *et al.* (78) collected hepatic lymph from the rat in chronic experiments and reported an average flow of 1.5 ml in 12 hours (12 rats). This rate of flow was increased to an average of 5.1 ml in 12 hours (6 rats) following biliary obstruction.

The role of liver lymphatics in the problem of ascites is discussed by Yoffey & Courtice (234). They point out that in the shifts of fluid which take place when ascites develops, three major sets of lymphatics are involved: lymphatics of the alimentary tract, liver lymphatics, and lymphatics of the diaphragm. All three are capable of carrying very large volumes of lymph, much greater than lymphatics from any other region of the body. Only in extreme circumstances and in the presence of severe disease does gross ascites become evident. Baggenstoss & Cain (10, 11) studied the relationship of hepatic hilar lymphatics to ascites in man. In various conditions associated with ascites, they found these structures increased in size and number when ascites was caused by cirrhosis of the liver or congestive heart failure but not when it was caused by neoplastic involvement of the peritoneum or by renal disease. Other clinical and pathologic conditions associated with ascites which revealed an increase in lymphatic vessels at the hilus were lupus erythematosus, fatal virus hepatitis, and massive liver involvement by neoplasms.

Pulmonary Lymphatics and Edema

There is a very large literature on the anatomy and pathology of the pulmonary lymphatic system but there is comparatively little information on the function of the widespread lymph vessels in the lungs. Warren & Drinker (216) were the first to collect lung lymph in 1942 when they succeeded in cannulating a large lymphatic in the anterior mediastinum of dogs. In 18 animals, they reported an average lymph flow of 1.1 ml per hour and an average protein concentration of 3.7 g per 100 ml. As they realized, their experiments were subject to the criticism that the thorax was open and the usual intrathoracic pressure absent. To obviate this difficulty, they and subsequent investigators turned to collection of lymph from the right duct. This procedure, although eliminating the above objection, introduces other variables. The right duct, as usually cannulated in the dog for lymphatic studies, not only drains the lungs but also carries lymph from the heart, right side of the thorax, and part of the convex surface of the liver. It is thus difficult to quantify the contribution of the lungs to total right duct lymph flow. However, since the contribution from thorax and liver are small, it is probably valid to assume with Drinker (60) that "in the quiescent, anesthetized dog the amount of lymph collected from the right duct expresses the lymph delivery from the contracting heart and moving lungs. If cardiac activity is kept reasonably constant, the quota of right

duct lymph arising from the heart is constant, and variation in output reflects conditions in the lungs."

A second variable is introduced by the occasional occurrence of anastomotic connections with the thoracic duct and thus free flow between the two ducts. Freeman (76) found anastomotic connections in 12 out of 25 carefully injected and examined animals. In the living animal, the presence of anastomotic connections is obvious if right duct lymph is milky rather than clear or becomes milky and increases in rate of flow after pressure upon the abdomen, a maneuver which is very effective in increasing flow from the thoracic duct but not from the right duct. Drinker (60) also suggested that shifting from natural breathing to artificial respiration through a tracheal cannula was a useful test, since artificial respiration increases right duct flow but reduces thoracic duct flow. Further tests can be made by introducing T-1824 dye into one of the lungs via a long catheter or by injecting the dye into the paw or a leg lymphatic. The former procedure results in coloring only right duct lymph if no anastomotic connections are present; the second procedure results in coloring only thoracic duct lymph. Using these tests, our experience has been that fewer than 20 per cent of dogs show functional anastomotic connections.

It is interesting that, in spite of the difficulties described as inherent in the study of right duct lymph, estimations of its flow and protein concentration are not too different from those originally reported by Warren and Drinker for lymph collected from the mediastinal lymph duct, and the protein concentrations are similar to those found in leg and cervical lymph. Thus Courtice (47) found that the average flow from the right lymph ducts of dogs was 2.3 ml per hour and the average protein concentration was 3.7 per cent, levels similar to those found in our laboratory (197). As Yoffey & Courtice (234) point out this would amount to about 2 g of protein daily or 3.6 per cent of the total circulating plasma proteins. The lymph flow is small in terms of the rich blood supply of the lungs. It should be borne in mind, however, that these experiments were done on anesthetized dogs in the supine position and levels of flow and concentration may only at best reflect minimum values.

The pulmonary circulation is a low pressure system and pulmonary capillary pressure is ordinarily less than plasma colloid osmotic pressure, a situation conducive to "dry" lungs. According to the Starling principle, edema would be expected to occur either when capillary filtration pressure was high or protein concentration reduced. Paine *et al.* (163), using the

heart-lung preparation, showed this to be true in experiments in which *a)* they lowered the plasma proteins by plasmaphoresis or by replacement with Locke's solution, and *b)* they elevated hydrostatic pressures by imposing a left ventricular overload. The onset and progression of pulmonary edema were always attended by an increase in the flow of lymph from the right thoracic duct. They conclude that measurement of an increased pulmonary lymph flow is a reliable indicator of the presence of pulmonary edema. Uhley *et al.* (210) and Rabin & Meyer (176) also studied the relationship between pulmonary hypertension, lymph flow, and edema. The former investigators devised a technique to collect pulmonary lymph flow more completely. Instead of cannulating the right lymphatic duct, they create a chamber within the right external jugular vein which traps lymph between the outside of a tube secured in the vein and the vein wall. Lymph is removed from the chamber by a polyethylene catheter. In 13 anesthetized, open-chest dogs under artificial respiration they found average lymph flow to be 0.3 ml per hour. This value is considerably less than that found by others, as indicated above. Elevation of pulmonary venous pressure to 30 mm Hg by introduction of a balloon into the left atrium resulted in an increase in lymph flow to an average of 1.14 ml per hour, the rise occurring about 15 min after inflation of the balloon. After maintenance of elevated pulmonary venous pressure and progressive increase of lymphatic flow for approximately 30 min, critical pulmonary edema ensued. The protein content of lymph paralleled lymph flow. Both increased lymph flow and pulmonary edema were generally promptly decreased with relief of the high pulmonary venous pressures. The authors conclude that the small absolute increase in right duct lymph suggests that lymphatics were unable to function significantly to relieve the acute pulmonary edema. Rabin and Meyer raised left atrial pressures by means of previously appropriately placed snares and found that, with this method, an acute elevation of left atrial pressure could be precisely controlled at any desired level up to a mean of 60 mm Hg in dogs with an intact thorax. Right lymphatic duct flow did not increase at acutely elevated left atrial mean pressures below 25 mm Hg, whereas flow increased 3- to 4-fold at mean pressures above 25 mm Hg. The total amount of lymph at maximum flow, however, was only 0.3 ml per min. Lymph flow remained elevated for as long as 1 hour after left atrial pressure was restored to normal. Pulmonary edema did not occur readily when left atrial mean pressure

was elevated only slightly above plasma oncotic pressure. It was observed only after a considerable elevation of left atrial pressure, above plasma oncotic pressure, was maintained for a period of one-half hour or more. Chronic elevation of left atrial pressure was achieved in 15 dogs. Left atrial mean pressure varied from 10 to 23 mm Hg. The dogs were followed for 10 months. Right lymphatic flow did not increase at chronically elevated mean pressure below 25 mm Hg. They did not study flow at higher pressures because they were unable to sustain left atrial mean pressure above 25 mm Hg in any dog in the chronic group. The animals that were brought to left atrial mean pressure between 30 to 40 mm Hg, and in which these high levels were presumably maintained, were found dead in their cages with pulmonary edema 1 to 2 days after the snare was tightened.

Drinker, while admitting that hemodynamic changes might be responsible for pulmonary edema, stressed the importance of changes in capillary permeability due to anoxia (60). He believed that "increased pressure in the pulmonary capillaries does not readily cause recognizable pulmonary edema unless coupled with heightened permeability, most frequently due to anoxia." His conclusions were based on a variety of experiments by him and his group (65, 216, 217). Thus, forced breathing of dogs against resistance without hypoxia did not cause pulmonary edema, although right duct lymph flow was augmented. On the other hand, when anoxia was present under the same circumstances, increased lymph flow and pulmonary edema were evident. Increased capillary filtration, according to Drinker, results in accumulation of fluid in the alveoli, interfering with oxygen uptake. A vicious cycle is set up as the hypoxia further increases capillary permeability and filtration. Courtice & Korner (48), on the other hand, failed to observe pulmonary edema when they made animals breathe a mixture containing 11 per cent oxygen. They believe that the results of the Drinker group can be equally well explained by postulating an increase in filtration pressure rather than changes in capillary permeability. There is considerable evidence to indicate that the permeability of systemic capillaries does not change at the levels of anoxia produced in the Drinker and in the Courtice and Korner experiments, and the latter correctly conclude that there is no evidence to indicate that the permeability characteristics of the pulmonary capillaries are different with respect to anoxia. Courtice and Korner gave large infusions of Ringer-Locke's solution to rabbits breathing low oxygen. The presence of anoxia led to edema

at a lower level of infusion than when anoxia was not present. The authors believe that this effect can be explained by the hemodynamic changes observed (decrease in cardiac output, systemic vasoconstriction, etc.) without postulating an increase in permeability. It may be pertinent in this connection, however, that Fishman *et al.* (71) recently reported that acute anoxia in human subjects produces a rise in cardiac output and that significant changes in pulmonary arterial pressure (average 7 mm Hg) are not found except when the arterial blood oxygen saturation is below 85 per cent. It also appears that acute hypoxia does not affect the thoracic blood volume (80).

The conclusions of Courtice and Yoffey should also perhaps be modified in light of more recent findings in our laboratory (197). We injected radioactive iodinated serum albumin and dextran fractions of average molecular weights of 51,000 to 255,000 into dogs anesthetized with Nembutal and followed concentration changes in plasma and thoracic and right duct lymphs for 4 to 6 hours. At this time, when a "steady state" had been established between plasma and lymph, we infused 40 ml per kg of 5 per cent serum albumin in 0.9 per cent saline. This resulted in a significant and striking increase in the concentration of the injected radioactive iodinated albumin and dextrans in right duct and thoracic duct lymph in spite of increased lymph flows. We interpreted these results (and earlier ones) to be the result of "stretching" of capillary pores as a result of raised hydrostatic pressure resulting from the expanded blood volume. It is conceivable that the hypoxia in Courtice and Korner's experiments may have served to exaggerate this phenomenon of the capillary wall. It is interesting, in this connection, that the possibility of pore stretching was suggested by Casten & Kistler (40) as an explanation of the acute pulmonary edema which they observed in mice and rats following blast injury and irradiation. They hypothesized: "The intercellular cement substance of capillary walls is postulated to consist of processes having elastic properties that tie the cell walls together. These processes are assumed to be normally under tension. If the intracapillary pressure increases, but remains below a critical value, the tension of the intercellular processes may be still sufficient to hold the cell mosaic tightly together and prevent gross fluid leakage. If the internal pressure exceeds this critical value, then the elastic processes may be stretched to a degree which causes the cell mosaic to be separated, and thereby permit gross fluid effusion to occur. With still greater internal pressure, the processes may be stretched beyond their elastic

limit, hereby producing an irreversible damage to the capillary wall. It is assumed that in the extravasation stage following acute radiation damage, the elasticity and the stretchability of these processes are greatly reduced."

It should be obvious from the brief review given that, in discussing the pathogenesis of pulmonary edema, we are concerned with a syndrome, like circulatory shock, in which many factors may be operative. In an individual case, a single factor may produce indeterminable effects unless it is very powerful. On the other hand, several factors may combine to produce the syndrome at a threshold lower than that necessary for each to act singly. In the final analysis we must assume that in the healthy animal, fluid and proteins which leak from the capillaries are drained off as an equal amount of lymph. Pulmonary edema arises when capillary filtration exceeds the point where the lymphatic drainage is adequate to maintain the relatively "dry" state of pulmonary tissue. This concept, that pulmonary edema results from a relative deficiency in lymph drainage is further supported by the experiments of Földi and his collaborators (75). They studied dogs in which they had experimentally produced mitral insufficiency, mitral stenosis, or bilateral vagal section and ligated the right and thoracic lymph ducts and lymph nodes of the anterior mediastinum. Only tying off the lymphatic supply failed to produce edema as did each experimental procedure under control conditions. When the procedure was combined with lymphatic ligation, however, edema ensued in most animals. Failure to occur under the combined procedure was correlated with lack of lymph congestion presumably to incomplete cutting off of lymph drainage.

Cardiac

The lymphatic supply of the myocardium was first described by Rudbeck in 1653 and has been debated ever since, particularly as to whether myocardial lymphatic capillaries exist. Patek (167) described three plexuses, subendocardial, myocardial, and subepicardial. The subendocardial vessels comprise capillaries in a single plane which drain into the myocardial plexus, a profuse system of interconnected capillaries. According to Patek, there were no efferent lymphatics but only anastomoses with the subepicardial system. Rusznyák *et al.* (188), however, review more recent work of Zhemcherzhnikova and Zhdanov showing that "the musculature of the ventricles in man contains reticularly arranged true lymphatic capillaries.

The loops of these capillaries are situated along the fasciculated muscles." According to these workers, the lymphatic system of the epicardium consists of a double, intercommunicating deep and superficial plexus. The efferent lymphatics are chiefly situated subepicardially, i.e., on the surface, and follow the branches of the coronary artery. The lymphatic trunks of the anterior surfaces of the two ventricles unite to form two lymphatics which run in the anterior longitudinal sulcus from the apex to the base of the heart. The lymphatic which unites the lymph vessels of the posterior surface of the left ventricle runs in the posterior longitudinal sulcus and reaches the anterior surface of the heart in the coronary sulcus. Uniting below the left auricle, these lymphatics form the heart's main collecting lymph vessel which drains into a bifurcation or laterotracheal lymph node. The lymphatics of the posterior and part of the anterior aspect of the right ventricle unite in the right efferent main lymphatic trunk which starts in the posterior longitudinal sulcus, passes over to the anterior surface of the aorta and runs along the surface of the right auricle to the cranial mediastinal lymph node which usually lies on the aortic arch at the origin of the left common carotid artery.

Miller *et al.* (146) have recently raised the question as to whether lymphatic vessels exist in the heart valves of the dog. They examined mitral valves in three groups of dogs: 1) stock dogs killed during the course of other laboratory experiments, 2) "sham"-operated dogs, and 3) dogs in which surgical obstruction of cardiac lymphatic drainage was produced and which were then killed at varying periods of time after surgery. Only an occasional thin-walled channel was found on histological study in the first two groups. However, numerous channels, presumed to be lymphatics, appeared in animals with obstructed lymph flow. The authors believe that interference with lymph flow may play a direct role in heart valve scarring and may provide an additional clue to the mechanism of progressive valvular fibrosis in the years following an inflammatory insult (such as rheumatic valvulitis). These authors also reported ventricular endomyocardial pathology produced by chronic cardiac lymphatic obstruction in the dog (145). Their results are similar to those previously described by Rusznyák (187) who reported many variations in the anatomy of the cardiac lymphatic system. They did not, however, find cardiac lymphatics entering the thoracic duct as Rusznyák reported. They found interstitial edema most often with dilatation of lymph capillaries. Disseminated focal necrosis in the myocardium was pres-

ent in 3 dogs and left ventricular subendocardial hemorrhages in 7 of 17 dogs. They describe other changes and point out the merit of further investigation of cardiac lymphatics and the relationships of disturbances of their function to pathologic states. Rusznyák and co-workers have also described the results of similar experiments done by their group. They report in detail the electrocardiographic changes seen after cardiac lymphatic obstruction and after ligation of the coronary sinus and cardiac lymph nodes. They also emphasize the possibility that lymphatic congestion may play an important role in the pathogenesis of mitral stenosis and other cardiac diseases.

Drinker and his colleagues (64) are the only group to date who have collected and studied cardiac lymph. They reported measurements of flow in 10 dogs as varying between 0.31 to 1.65 ml per hour (average 0.8 ml/hour) with no correlation between dog weight, heart weight, blood pressure, and lymph flow. Since only one lymphatic was cannulated and since there are usually two main efferent trunks, the total flow was probably approximately twice the values obtained. This would mean that about 60 to 70 per cent of the total right lymph duct flow comes from the heart. The lymph always contained a relatively high concentration of protein. The average for 18 dogs was 3.69 per cent with a range between 2.50 to 4.73 per cent. Since right duct lymph contains approximately the same concentration, this suggests that cardiac and lung lymph have about the same concentration of protein. This is also supported by the values obtained by Warren & Drinker (216) in collection from a large lymphatic in the anterior mediastinum. Thus there is in the heart, as in all other tissues studied, a continuous leakage of protein from the capillaries and the rhythmic contractions of the cardiac muscle insure its rapid removal by the extensive lymphatic plexuses. These investigators also found that cardiac lymph flow increased after the injection of epinephrine and ephedrine, the rise appearing to be correlated to the increased cardiac work. Experiments with a Starling heart-lung preparation designed to simulate exercise (increased input and peripheral resistance and addition of epinephrine) showed a marked increase in lymph flow to 24 ml per hour. As Yoffey & Courtice (234) point out, even if we accept a figure of 18 ml per hour, a hound engaged in a 12 hours' chase would be putting out 216 ml of cardiac lymph. With a heart weight of 91 g, this would mean 2.4 ml of lymph per g of heart during the 12 hours.

Renal

Although a relatively extensive literature has accumulated concerning the distribution of kidney lymphatics and their possible role in clinical disorders (88), the physiological role of renal lymph is less well documented. This is due to the difficulty in cannulating the vessels because of their location and extremely small size. The main hilar trunks are particularly inaccessible to cannulation, whereas capsular lymphatics, although more accessible, are quite small and difficult to cannulate. This has led some investigators to the highly unphysiologic compromise of eviscerating animals and collecting thoracic-duct lymph on the assumption that this lymph was now derived solely from the kidney.

The first physiological experiments on renal lymphatics were made by Ludwig & Sawarykin (129), who showed that ligation of a ureter was followed by dilatation of efferent renal lymphatics. They did not study lymph flow or composition under these conditions, but their experiments form the basis of a more recent elaborate study by Babics and his collaborators (7, 8), whose work will be discussed later. Sugerman *et al.* (204) were probably the first to collect renal lymph directly and begin its characterization in dogs. They cannulated both capsular and hilar lymphatic trunks and reported a wide fluctuation in flow and protein concentration. The slower the lymph flow, the greater was the concentration of protein. Their average figure for flow from 11 dogs was 0.0232 g per min (1.392 g/hour) and for protein concentration 1.84 g per cent. Of interest was the finding of a higher average urea concentration in renal lymph (69.7 mg %) than in plasma (53.1 mg %). In some animals, the lymph urea concentration was considerably higher than that in plasma of the renal artery or vein. These findings posed two questions: 1) Do the renal lymphatics drain only the larger collecting ducts of the kidney, thus accounting for the high urea content of its lymph? 2) Is renal lymph derived from tubular reabsorbed fluid, the blood plasma, or from both types of fluid? Attempts to answer these questions were made by Kaplan *et al.* (107) who determined and compared the glucose content of renal and cervical lymph samples as well as their inulin content during an intravenous infusion of inulin. The average concentration of glucose in 8 renal lymph samples was 92.7 mg per cent and 101.9 mg per cent in 8 cervical lymph samples. They concluded that this high glucose concentration in renal lymph suggests that renal lymph could not be derived exclusively from the relatively sugar-

free fluid contained in the larger collecting ducts of the kidney. The average concentration of inulin in renal lymph from 8 dogs was found to be 82.5 mg per cent or 94 per cent of the plasma concentration. The authors considered these results as evidence that the composition of renal lymph is determined by the character of both tubular reabsorbed fluid and renal blood plasma. If it were derived exclusively from the renal tubular reabsorbed fluid, its inulin content would be practically nil and if it were derived exclusively from renal blood plasma, its inulin content would be equal to that present in plasma.

Swann and his colleagues (205) reported measurements on renal capsular lymph from 5 dogs. Lymph flow was between 0.1 to 0.3 ml per hour. They also found urea concentration of renal lymph to be higher than plasma and glucose concentration to be lower. They found total protein content to be quite constant at about 3.2 g per cent, about half that present in plasma, and failed to observe the inverse relation of protein content to lymph flow reported by Sugerman *et al.* Electrophoretic separation of the proteins showed that their distribution in lymph was similar to that in plasma.

About 5 years ago, my colleague, Dr. S. J. LeBrie, and I began a comprehensive study of renal lymph as part of a general study of lymph and lymphatics. We have collected renal capsular lymph in a variety of experimental situations which will be detailed below. We have found the lymph flow to be quite variable and unrelated to sex, age, or size of the animal. The average control flow for 63 dogs studied up to the present time is 0.0128 ml per min or 0.768 ml per hour. Total protein concentration for 40 dogs averages 2.76 g per 100 ml or about half of plasma concentration.

We find protein distribution to be similar to that of plasma, confirming the findings of Swann *et al.* All plasma proteins, including fibrinogen, are present in renal lymph. Potassium concentrations appear to be identical in lymph and plasma. We previously reported (121) that the average lymph sodium concentration for 30 dogs was 11.3 per cent higher than in plasma. Addition of more data and refinement of experimental procedures suggests that this value may be too high and the difference may or may not be significant. Limited data on osmotic pressure also have been equivocal. Data on 30 dogs show lymph chloride concentration to average 13 per cent higher than plasma, a difference which is statistically significant. We have some indication that bicarbonate concentration is lower in lymph than in plasma. Obviously

we need more data to clarify the situation with respect to these constituents. These data are being accumulated.

It is of interest to compare renal lymph flow with urine flow in the same kidney. It is reasonable to assume that there are at least ten lymphatics draining each kidney. Using the average flow which we obtained from one lymphatic, the average total lymph flow from both kidneys would amount to 0.128 ml per min, which is approximately half of the average amount of urine flow. In some animals with high lymph flows, the amount of capsular lymph drained equals the amount of urine formed. Similar admittedly rough calculations for protein yield a value of 10.2 g of protein returned to plasma per day via capsular lymphatics of both kidneys. It should be emphasized that these are average values for the anesthetized dog and probably reflect minimum levels.

Renal lymph flow is markedly increased by raising venous pressures. This was first shown by Schmidt & Hayman (195) and later confirmed by Katz & Cockett (109) and by us (123). Schmidt and Hayman analyzed the changes in thoracic duct lymph flow in eviscerated, hepatectomized, and uninephrectomized dogs following ligation of the remaining functional renal vein. They concluded that the increase in renal lymph flow was responsible for the observed rise in thoracic duct lymph flow when venous pressure was raised. Katz and Cockett likewise concluded that changes in renal lymph were responsible for changes in thoracic duct lymph which they observed. They observed an increase in thoracic duct lymph flow and sodium concentration as well as a decrease in urinary flow and sodium concentration when venous pressure was raised. The changes occurred only when the kidneys were intact. Haddy and his colleagues (94), in experiments designed to study pressure and flow relationships in the kidney, also reported that renal lymph flow increased as a function of venous pressure. In our experiments, we collected capsular lymph and raised the venous pressure by partially occluding the inferior vena cava with a balloon catheter. We also measured protein and electrolyte changes. Renal lymph flow increased about five times during the periods of increased venous pressure and the flow from one lymphatic equaled and often exceeded urine flow from the same kidney. Electrolytes and protein levels changed proportionately except at high venous pressure levels (30–35 cm H₂O) when disproportionately high levels of protein were found in renal lymph.

In discussing the significance of the changes in lymph

phatic flow and composition produced by increased venous pressure, we suggested that they might have some bearing on the problem of plasma volume increase and sodium retention in congestive heart failure, a syndrome in which venous pressures not infrequently approximate the high levels used in our study. We pointed out that under conditions of significantly increased venous pressure the total lymph flow from both kidneys may amount to as much as 2400 ml per 24 hours. This would represent a total of ± 379 meq of sodium not excreted by the kidneys but retained by the lymphatic system. A study of kidney lymph flow in postural proteinuria might also be of interest. Bull (32) believes that "A rise in pressure in the inferior vena cava is produced by compression of the vessel against the spine by the posterior surface of the liver. This pressure is conducted back to the kidney, inducing passive congestion and proteinuria. The compression occurs when the subject is in a lordotic posture and when the anterior surface of the liver rotates inferiorly. This rotation of the liver normally occurs when the subject is lordotic and is maximal in the erect lordotic posture." Goodwin & Kaufman (89) suggest the possibility of thoracic duct or cisterna chyli lymphatic obstruction and retrograde lymph flow as a possible explanation of the proteinuria and cite the report of Lowgren (128) as suggesting this explanation.

If we agree that one of the primary functions of the lymphatic system is to return to the vascular system those proteins and other large molecules which have leaked out of the blood capillaries, our accumulated data emphasize that kidney lymphatics are no exception. This is a function of considerable importance for the kidney. Maintenance of a relatively low concentration of interstitial protein is necessary for the maintenance of the countercurrent action in the kidney. This concept visualizes the vasa recta as a countercurrent exchanger carrying off salt and water. Gottschalk & Mylle (90) believe the efficiency of the countercurrent exchange in the vasa recta to be critical, "for they probably remove not only the blood entering the medulla, but also the water that diffuses from the thin descending limbs of the loops of Henle and the collecting ducts. This water, with solute isosmotic for the particular level of the medulla, presumably moves into the vasa recta because of the gradient of its chemical potential established by the colloid osmotic pressure of the plasma proteins, since the hydrostatic pressure in the capillaries and interstitium are the same." The gradient of colloid osmotic pressure between the interstitium and the plasma can be main-

tained only if the colloid osmotic pressure of the interstitium is kept well below that of the plasma. We believe that this is an important function of renal lymphatics, the maintenance of a relatively low oncotic pressure in the interstitium and thus the establishment of a gradient with the higher oncotic pressure within the vasa recta. Thus, as the lymphatics carry off plasma protein that has pooled in the medullary interstitium, the colloid osmotic pressure of these proteins draws water with a higher or lower solute concentration, depending upon the level of the countercurrent gradient at which the lymph is formed. The medullary and cortical lymph passes into lymph collecting trunks, mixing the two and thus reducing the electrolyte concentration and osmolarity. Some collecting trunks leave the kidney through the cortex while others follow the path of the artery and vein to the hilus. When renal venous pressure is increased, more protein is lost in both cortex and medulla due to increased hydrostatic pressure. Thus, although filtration of protein increases as does water, the concentration of filtered electrolytes does not increase over control values. We assume that filtered electrolytes from cortical capillaries are isosmotic with both plasma and cortical interstitial tissue, while filtered electrolytes from the vasa recta are hyperosmotic to plasma but isosmotic to the countercurrent gradient in which they lie. Thus, if these fluids are mixed, one might expect the concentration of sodium in milliequivalents per liter to remain unchanged. This is essentially what we find.

In terms of the above discussion, we would expect ligation or obstruction of lymphatic outflow to produce edema and significantly alter kidney function. Kaiserling & Soostmeyer (105) succeeded in tracing the lymphatic vessels to the main hilar branch in rabbits and in tying it off. The kidney began to swell immediately and had reached double its original size within 10 to 15 min as a result of massive interstitial edema. There was a marked increase in urinary output on the side with lymphatic ligation and, significantly, the urine from the experimental side had a specific gravity of 1.013, whereas the control side had a specific activity of 1.035. Later, the urine flow diminished, proteinuria was present, and the kidney and its parenchymal cells degenerated 8 to 10 days after the lymphatics were ligated.

These and other similar studies and their implications are discussed at length by Babics (7, 8) and Rusznyák *et al.* (189).

Earlier mention was made of the fact that the first experiments on renal lymph were those of Ludwig &

Sawarykin (129) who noticed that ligation of a ureter was followed by dilatation of the efferent renal lymphatics. Similar observations have since been made by many investigators (88, 153, 154, and LeBrie and Mayerson, unpublished) who have also shown that renal lymph flow is significantly increased. Katz (108) measured renal lymphatic pressure in two dogs with pyelonephritis and found the pressures to rise when either the renal vein or the ureters were compressed. It is apparent that the renal parenchyma shows no significant changes for a number of weeks after the experimental ligation of the ureter; the only histopathological symptoms that can be observed for a considerable time are a high degree of interstitial edema and marked dilatation of lymphatics. Babics & Rényi-Vámos (7) ascribe the survival and continued performance of the hydronephrotic kidney to the fact that urine passes from the renal pelvis into the interstitial space of the kidney where it is continuously absorbed into lymphatics. Histamine is presumed to be liberated, increasing capillary permeability and transudation of protein. This protein, too, is carried away by the lymphatics. If, on the other hand, the lymphatics are also tied off, necrosis is seen within a few days [see Babics & Rényi-Vámos (7) and Rusznyák *et al.* (189) for detailed discussion].

The general effect of diuretics is to increase renal lymph flow. Reference has been made to the work of Schmidt and Hayman who showed this to be true for phosphate, sodium chloride, and caffeine. We have collected renal capsular lymph in dogs during diuresis produced by sodium chloride, urea, mannitol, and mercury (LeBrie and Mayerson, unpublished). Under the conditions of our experiments, we obtained the most marked diuresis with urea and mannitol and the least with mercury. Mannitol produced the greatest increase in lymph flow (average 10 dogs = 587%), while mercury and urea produced the least (Hg, 15 dogs, 42%; urea, 7 dogs, 41%). These experiments are being continued and attempts are being made to elucidate the mechanism of the changes in flow, electrolyte and protein concentration, and to explain the differences seen with the different diuretics.

We have also studied the influence of uranium-nitrate injury on the flow and composition of renal lymph (122). Lymph flow was increased approximately 15 times in the experimental animals. Likewise, the increase in lymph flow with mannitol infusion was about twice as great in the experimental animals (1000% increase) as in control animals (542% increase). The experimental animals showed a significant proteinuria and decreased urine flows,

and the data appear to be consistent with the histologic findings of primary damage to the distal segment of the proximal tubule.

The finding of an increased lymph flow when ureters are obstructed and diuretics are administered has given rise to the concept emphasized in clinical literature, that the renal lymphatics act as a "safety-valve" mechanism, capable of taking the extra load from the kidney under conditions of overload. Backflow from the kidney pelvis to the renal lymphatics has also been suggested by experiments of Murphy & Myint (153) and Goodwin & Kaufman (89). The former introduced glucose and the dye T-1824 into the renal pelvis and found these substances earlier and in greater concentration in lymph of the cisterna chyli than in renal or femoral blood. The latter injected radioactive Diodrast into the renal pelvis during ureteral occlusion and found the same radioactivity at the same time in thoracic duct lymph and in the control vascular area. More work along these lines is needed, particularly defining the mechanisms involved and the effects of pyelolymphatic backflow in kidney disease. However, it may be pertinent to emphasize, as has been previously suggested, that the general function of the lymphatic system is to act as a "safety valve" and as an accessory circulation, clearing the interstitium of excess substances which leak out of or are not absorbed directly into the blood stream and returning them to the blood circulation. This is not a peculiar or special function of renal lymphatics. Thus, an overload of the circulatory capacity as produced by a large intravenous infusion results in an increased lymph flow, etc. The particular importance of lymph with respect to normal renal function lies in the fact that the oncotic pressure of the interstitium must be kept low in order for the vasa recta to act as a counter-current exchanger. In the absence of adequate lymph drainage the kidney becomes unable to concentrate urine (105).

LYMPH AND LYMPHATICS IN SHOCK

Anaphylactic Shock

Petersen & Levinson (173) found that injection of antigen into dogs resulted in an increased permeability of splanchnic endothelium and subsequent reaction of the hepatic parenchymal cells with the antigen. In further work, Petersen & Hughes (172) showed the injection of egg white into dogs sensitized

to egg albumin to result in an immediate and marked increase in thoracic duct lymph flow with increased concentrations of calcium, amino nitrogen, and magnesium, and decreased concentrations of sodium and potassium. They did not measure proteins. Dragstedt and his colleagues (55-57, 82) reported that, in the dog at least, the vasomotor symptom and death occurring in anaphylactic shock are brought about by the sudden discharge into the circulating blood of a vasodepressor, smooth muscle-stimulating substance which is apparently histamine. They were able to detect this substance in blood and thoracic duct lymph for brief periods of time after the assaulting or shocking dose of serum, and to correlate its appearance with varying grades of severity of the shock in such a way as to indicate that it had a causal relationship to the shock symptoms. More specific results were recently reported by Logan (127) who showed that bovine globulin is a satisfactory antigen for sensitizing rats when given intraperitoneally simultaneously with *Bordetella pertussis* vaccine. Intestinal lymph of animals so sensitized contained increased amounts of histamine when collected 6 min after intravenous injection of the shocking dose. The amount of lymph histamine was roughly proportional to the degree of shock. The rate of lymph flow increased 8 to 25 times during the 12 min immediately after administration of the shocking dose and the lymph contained 0 to 0.02 μg histamine per ml, an amount similar to that in plasma.

The lymphagogue action of histamine is well known and can readily be demonstrated by the intravenous injection of small amounts of the substance (95). This effect has usually been ascribed to dilation and increased permeability of capillaries, although the exact mechanisms involved have never been clearly defined. Ruzsnyák *et al.* (189) review much of the evidence and report experiments done in their own laboratories by Szabó and Magyar. The latter injected a dextran fraction of approximately the same molecular weight as albumin simultaneously with histamine and with Evans blue. In dogs, flow of intestinal and hepatic lymph increased two to three times and remained high; appearance of dextran and dye-labeled albumin in lymph was much sooner as was equilibration between plasma and lymph. The authors believe they have ruled out the factor of increased filtration pressure in favor of increased capillary permeability. Repetition of the same experiments in cats gave entirely negative results, i.e., no increased lymph flow or accelerated equilibration. The authors explain these differences as being due

to the fact that in the dog not only the capillaries and small veins but also the arterioles are dilated by histamine (and only the larger visible arteries constricted), while in the cat this constrictor effect begins more peripherally in the arterioles. The authors take issue with the assumption by Krogh (117) that dilation of capillaries leads to increased permeability, since capillaries dilate in the cat quite as much as in the dog without showing increased permeability.

Changes in blood coagulability are among the important findings in the anaphylactic reaction (67, 104) and result from the release of heparin from the liver. The possibility that this substance may be transported from the liver to the blood stream by way of the thoracic duct was first suggested by Gley (87) who found that ligation of the liver lymphatics prevented the incoagulability of blood following peptone shock. White & Woodward (228-230) showed that the incoagulability of thoracic duct lymph following an anaphylactic or peptone-induced shock is due to heparin and that the main portal of entry for this substance into the blood stream is via the thoracic duct from the liver. The concentration of heparin in lymph in these situations was greater than in arterial or hepatic venous blood and it was frequently present only in thoracic duct lymph. When heparin was given intravenously the concentration of heparin was the same in thoracic duct lymph and in plasma. Furthermore, heparin did not appear in cervical or right duct lymph unless it first appeared in blood. Removal of the liver prevented the appearance of heparin in peptone-shocked dogs. These findings confirm the liver as being the origin of heparin under these circumstances. Heparin was not released into thoracic duct lymph or blood during a hemorrhage-induced shock, thus ruling out hypotension as a factor in the heparin release. It is suggested that the release of the heparin may depend upon limited cellular reactions and not upon general cellular activity.

Traumatic Shock

There has been considerable interest in studying the participation of the lymphatic system in traumatic shock. These studies have taken different forms. The Hungarian workers (188) have done a considerable amount of work in which they have measured lymph flows from various areas and used the composition of lymph as a measure of capillary permeability. There has been a recurrent interest in the presence or absence in lymph of a "toxic" substance which may or may not have come from the plasma.

The question as to whether capillary permeability is altered in shock has been a hardy perennial. A detailed discussion of this topic would be out of place at this point. It is, however, appropriate to call attention to the studies of the Hungarian group referred to above in which they have made extensive observations on the role of lymph and lymphatics in dogs during and after traumatic shock. They have used the same general approach as we have used (141, 219) of introducing dextrans of molecular weights similar to those of albumin and globulin into the blood stream, following their disappearance from the blood stream and their appearance in lymph from various regions. Since radioisotopes were not available to them, they used the dye, T-1824, which is known to bind onto albumin and thus constitute a label. Their results on control animals resemble in general those which we obtained; albumin or dextran of molecular weight of about 50,000 appeared in thoracic duct lymph within 10 min and, in their experiments, the average dextran concentration was 29 per cent of that in plasma at 15 min and about 75 per cent at 60 to 90 min. In tourniquet shock produced by arresting the circulation of the hind legs for 5 hours, they found a more rapid disappearance of the dextran from the blood stream but a much slower appearance and accumulation in thoracic duct lymph. At 90 min there was only an average of 43 per cent of dextran in the lymph. Lymph flow was considerably reduced. These workers also studied cervical lymph and, while their results were not definitive, it seems reasonably certain that the capillary permeability in peripheral regions was not increased. Attempts to find the reasons for the decreased thoracic duct lymph flow and the delayed appearance of protein and dextran were not successful. It was apparently not due to diminished hepatic-lymph formation or to lymphangiospasm. They interpret the faster disappearance of the dextran from blood as reflecting the increase in capillary permeability in the ischemic area rather than a generalized increase in permeability. One of the group (226) has extended some of the work to hemorrhagic and burn shock and again finds a decreased thoracic duct lymph flow which parallels the severity of the shock. He also interprets his data as denying any generalized increase in capillary permeability.

Since edema is prominent in the ischemic areas, these investigators went on to study the flow of leg lymph and the behavior of albumin and dextran in the hope of ascertaining whether the edema was due to an inability of the lymphatic system to cope with

an increased tissue fluid formation or whether there was injury to the lymphatics caused by the ligatures. Although the small lymph flow in leg lymphatics precluded quantitative data, there was no question of the direction of change and that protein leakage was increased in the ischemic area. The increased lymph flow argued against lymphatic injury or occlusion as factors in the edema production.

The occurrence of a vasoconstrictor substance in blood during shock induced by trauma, hemorrhage, and burns was reported in dogs by Page (161) and denied for ischemic compression shock (91). Rapport *et al.* (180) also reported the occurrence of a "toxic factor" in tourniquet shock in rabbits.

In 1943, Blalock (19) reported the results of experiments in which he produced crush injury in anesthetized dogs by applying a press to a hind leg. Thoracic duct lymph collected from these dogs after removal of the pressure and injected into other dogs brought on a decrease in blood pressure and death of some of the animals. Less marked results were obtained when trauma was produced by striking the legs with a blunt instrument. Blalock explained his results as due to the presence of a toxic substance in lymph of the traumatized animals. Katzenstein *et al.* (110) reported similar results in shock produced by tourniquets around the hind legs. These authors appreciated the possible vasodepressor effects of large doses of Nembutal which they used but showed that when narcosis was controlled to avoid vaso-depression, injection of thoracic lymph from normal dogs had no effect. In contrast, a fall in blood pressure followed in 50 per cent of the animals injected with lymph of shocked animals. The problem was further studied by Nathanson and his collaborators (155), who devised a method of producing tourniquet shock in dogs which permitted the collection of muscle exudate. They collected the exudate, which accumulated after muscle anoxia, and injected it into the same or recipient dogs (6). Shock was produced in only 25 per cent of the animals tested. The inconsistency of the presence of the toxic factor suggested that the factor was an extraneous agent, not present in the usual cellular constituents and metabolic products found in all muscle exudates, and possibly bacterial in origin. They further showed (235) that the toxic properties of a collection of pooled muscle exudates were contained in a nondialyzable fraction, could be salted out between 0.25 and 0.7 saturation with ammonium sulfate and were, therefore, probably protein in nature. The toxic substances were tentatively classified as an aminooxopeptidase and a

trypsinase which were present in the exudates. Freeman & Schechter (77) tested leg lymph obtained from dogs whose hind legs were traumatized or heated and found that it produced an increase in permeability as judged by leakage of dye when injected into recipient animals. Arterial and venous serum and plasma also contained a similar factor which increased capillary permeability, and the authors concluded that it was likely that the presence in lymph of a substance capable of producing an increase in capillary permeability is dependent upon the appearance, after trauma, of blood plasma in the lymph draining from the extremity. On the other hand, Lindner *et al.* (126) failed to find any evidence of a permeability factor either in lymph or plasma in shock produced by manipulation of the intestine. Their experience was similar to the earlier one reported by Dragstedt & Mead (57), who produced shock by sustained trauma with a padded hammer to one or both hind legs, by trauma to the intestine, or by a combination of the two methods.

Burns

Some work has been done on the study of lymph in burns. Aldrich (2) collected leg lymph from burned, anesthetized dogs and perfused it through rabbit ears. Blood flow as measured by drop rate definitely decreased when lymph from burned animals was used as compared to lymph from healthy dogs. No attempt was made to identify the vasoconstrictor substance.

Glenn and his colleagues, in Drinker's laboratory, studied the changes in lymph composition after leg burns produced with hot water in calves (85, 86, 170). Cervical and leg lymph was followed. Lymph flow in the burned legs was significantly increased as was the protein concentration of the leg lymph. Cervical lymph, however, did not show the increase in protein. Electrophoretic studies showed the occurrence of a new protein in the lymph from the burned leg, a component migrating with half the speed of γ -globulin. Cope & Moore (44) also reported a significant increase in capillary permeability following hot water burns of legs of dogs. They injected radioactive colloidal dyes into the blood stream and measured their appearance in leg, cervical, and thoracic duct lymph before and after the burn. They also injected radioactive bromine, which they found to appear in lymph from the three areas within 5 min and to reach equilibrium with serum in 20 min. In contrast, the colloidal dyes were slower in appearance in

lymph and no equilibrium was established with serum under control conditions. Following the burn, the concentration of radioactive colloids in lymph of the burned leg rose abruptly and approached that encountered after injection of radioactive bromine. The specific activity of protein was actually higher in lymph than in serum after the burn. In confirmation of Glenn *et al.*, they also found that the increased capillary permeability was usually restricted to the burned leg. A rise in colloid concentration in cervical lymph was observed in only one dog.

Permeability Factors

During the last decade, considerable interest has been aroused in the presence in plasma of endogenous substances which, when activated, induce pathological increases in capillary permeability (144). Two classes of natural mediators have been suggested: 1) the pharmacologically active amines, histamine, and hydroxytryptamine; and 2) proteases and products of proteolysis. This latter group includes the proteases of plasma (plasmin, the serum globulin permeability factors, and polypeptides like leukotaxine and bradykinin). The groups overlap in that polypeptides may act as histamine liberators. There is direct and indirect evidence that these substances participate in the mediation of the response to injury, but much more evidence is needed to define their role in the healthy animal and in animals suffering from hemorrhage, burn, or other trauma. It would be interesting to extend the observations of Miles & Wilhelm (144) to other substances, species, and experimental conditions. These investigators showed the presence in the guinea pig of the precursor (pro-PF) and the inhibitor (IPF) of one of the globulin permeability factors, both in intercellular perfusates of skin and in normal lymph from the cervical lymph ducts (143). It appears that the proteins constituting the pro-PF/IPF system of the blood, like other plasma proteins, pass continuously via the extravascular tissues to the lymph, and that the extravascular tissues, including the outer surface of the capillary wall, are bathed in tissue fluid containing pro-PF.

PERMEABILITY OF LYMPHATIC VESSELS

Although a considerable amount of work has been done relative to the permeability of blood vessels, we have very little definitive information regarding

permeability characteristics of lymph vessels. Light microscope studies suggested that lymph and blood capillaries are morphologically similar, a suggestion which has been confirmed by recent studies, particularly those of Casley-Smith & Florey (39a). These authors showed that there were no species differences in lymphatics of mice, guinea pigs, and rats, and that the lymphatics of the ear and the deep lymphatics of the diaphragm and colon were similar. In general, the structure of the lymphatic capillaries and lacunes appeared to be similar to that of blood capillaries. All the lymphatic endothelial cells contained many vesicles and caveolae intracellulares. No fenestrations in the endothelium were seen, but some intercellular junctions were patent, especially in diaphragmatic lacunes. The basement membrane was less regular than that of blood capillaries or of mesothelium and in many places, especially in diaphragmatic lacunes, it appeared to be absent. These results are similar to those of Palay & Karlin (164) and French *et al.* (77a). The absence of a definable basement membrane would not, as Casley-Smith and Florey point out, fully differentiate lymphatic from vascular endothelium, since the endothelium lining large blood vessels may have at best a very tenuous basement membrane. The significance of the absence of fenestrations in the lymphatic endothelium also remains questionable in the absence of definite information as to the importance of their presence in determining permeability characteristics. The significance of their other findings will be discussed further below.

The permeability pattern in lymphatics presents an interesting and challenging problem. It is obvious from the preceding discussion that proteins, chylomicrons, and lymphocytes are normal constituents of lymph as routinely collected from healthy animals. Experimentally, bacteria, viruses, red blood cells, graphite particles, etc. have been shown to penetrate the lymphatic system with no apparent difficulty. Lane Allen (1a) showed that every type of cell which occurs normally in tissue fluid and blood will penetrate lymphatic endothelium. He felt he had identified every cell of the hematopoietic series, except giant cells, in diaphragmatic lymph after intraperitoneal injection of bone-marrow suspensions. Likewise, he found that the entire series of lymphoid cells will enter through lymphatic endothelium. The large amount of literature published before 1956 describing these experiments has been thoroughly reviewed by Yoffey & Courtice (234). The more recent publications will be discussed later.

In spite of the apparent ease with which substances can penetrate into the lymphatic vessels, the available evidence suggests that once these substances are in the lymphatic system, they are retained and eventually find their way into the blood stream via the larger ducts. Thus MacCallum (132a) retroinjected the lymphatics of the diaphragm and failed to force suspended particles back into the peritoneal cavity, except when he used pressures sufficient to rupture the lymphatics. Hudack & McMaster (100a) injected dyes into the ears of mice and studied the escape of these substances from the lymphatics. They reported that poorly diffusible dyes (pontamine sky blue, Chicago blue 6B) which pass with difficulty out of blood capillaries into the tissues, tend to be retained by the lymphatic wall as well, whereas more highly diffusible dyes (trypan red, bromphenol blue, and Neptune blue) pass out with ease. Rusznyák *et al.* (189) have more recently reported similar results using fluorescent dyes (thiazine red, acridine yellow) in intestinal lymphatics of cats. Hudack and McMaster concluded that "all the evidence we have obtained supports the view that permeability of the lymphatic wall resembles the permeability of the capillary wall in its essential features and perhaps in its degree." Drinker & Field (61a) retroinjected lymphatics of the frog web with graphite acacia and found no passage of the graphite particles until rupture resulted from excessive pressure. Pullinger & Florey (175) found that when they injected graphite particles into ear lymphatics of the mouse, the fluid leaked out but the graphite particles remained. Similarly, Lee (124a) found that large particles of centrifuged, dialyzed India ink were retained in lymph vessels, whereas small particles passed through. Courtice & Steinbeck (50a) attempted to evaluate lymphatic permeability by injecting T-1824-labeled plasma proteins intraperitoneally into rabbits and collecting lymph containing the protein from the exteriorized thoracic duct. They found that the injected proteins were almost entirely absorbed by the diaphragmatic lymphatics. In further work (50b) they demonstrated that ligation of the parasternal lymph channels in rabbits, rats, and guinea pigs prevented the dye-labeled protein from reaching the circulation via the thoracic duct, but instead, after entering diaphragmatic and mediastinal lymph channels, it proceeded to leak into the mediastinum and pleural cavities. They concluded from these experiments that lymphatics leaked protein, a conclusion open to question in view of the obviously unnatural conditions of their experiments. Ligation of the parasternal lymph chan-

nels and the resultant increased intralymphatic pressure and distention of the lymph vessels might conceivably permit leakage of substances which ordinarily would be retained within the lymphatic vessels as has been previously shown to be true in earlier work cited above. This has been shown to be true of blood capillaries (197). Furthermore, the fact that Courtice and Steinbeck found no protein leakage when the ducts were not ligated suggests that the lymphatics of the anterior mediastinum, under normal circumstances, will not permit leakage of significant amounts of the protein which is contained by them.

In a recent study (168) we attempted to obtain answers to the questions: *a*) Does the capillary filtrate, once it is in the lymph ducts, empty without loss into the venous circulation or is protein free to pass out of the lymphatic vessels throughout their lengths? *b*) Does any protein pass into the blood capillaries? *c*) Is any considerable amount of protein phagocytized by the reticuloendothelial cells of lymph nodes? Furthermore, to what degree, if any, is lymph shunted to the blood stream through lymph-blood anastomoses without returning via the thoracic duct? Anomalous shunts, consisting of multiple outlets of right and left ducts, have been described as well as shunts between the right and left thoracic ducts in about 15 per cent of dogs (234, 197). One phase of our study involves the cannulation of a leg lymphatic in an anesthetized dog, the infusion into it of substances of different molecular weights, and obtaining and analyzing samples of thoracic duct lymph and plasma. The infused material thus travels through a number of lymph nodes, through lymphatic vessels of different sizes, and through capillaries.

The second approach to the problem is to utilize a preparation developed some years ago by Drinker and his group (63). One afferent and one efferent duct going to and from the popliteal node are isolated and catheterized with polyethylene tubing. All other lymphatics are tied off. Test substances are infused through the node from the afferent side and collections are made on the efferent side. Nodal and systemic plasma are also obtained and analyzed.

When radioactive iodinated albumin is infused into a leg lymphatic, there is a typical, consistent pattern of appearance of the albumin in thoracic duct lymph as shown in figure 5. There is a lag time of approximately 10 min between the start of the infusion into the leg lymphatic and the appearance of measurable amounts of radioactive albumin in thoracic duct lymph. This is followed by an abrupt rise to a plateau which is maintained at an approximately constant

FIG. 5. Concentration of dextran and I^{131} albumin in lymph and plasma. Dextran and I^{131} albumin solutions infused centrally into leg lymphatic of anesthetized dog at zero time at rate of 0.5 ml/min. Infusions of dextran and albumin stopped after 50 min and 0.9% saline infusion started at same rate for next 100 min. All values are corrected for free iodine.

level for the 50-min duration of the albumin infusion and for 10 min of a subsequent saline infusion. At this time, radioactivity in thoracic duct lymph falls sharply and continues to fall until the level approximates zero in about 140 to 150 min. Plasma radioactivity rises to a maximum concentration after 60 to 90 min and remains at this level for the remainder of the experiment. The maximum plasma concentration is less than 0.001 of the thoracic duct lymph concentration during its 50-min plateau period. Figure 5 also shows the similar behavior of dextran of approximately the same average molecular weight as albumin. It is apparent that these infused substances do not leave the lymphatic system and that they return to the circulation primarily by the thoracic duct. Actually less than 3 per cent of the infused material reaches the circulation by routes other than the thoracic duct, except in unusual cases of right and left duct anastomoses. The experiments

FIG. 6. Concentrations of urea in lymph. Same procedure as in experiment shown in fig. 5.

with the isolated lymph node preparation suggest that most of the 3 per cent or less not recovered from the thoracic duct goes into the blood stream via the popliteal node, and that there is little further loss in the other nodes through which the lymph passes on its way to the thoracic duct. We suspect that this is due to the fact that we are infusing under some pressure which is dissipated after the first node is passed. Nisimaru & Irisawa (156), in studying lymphatics of the frog's web, found that the permeability of injected lymphatic capillaries to particles of increasing sizes was directly related to increases in intraluminal pressure when applied via the lymph sac. Thus, patent blue dye escaped with 5 mm H₂O pressure, Congo red with 20 to 50 mm H₂O pressure.

We have tested a variety of substances of different molecular weights including dextran fractions, radioactive sodium (Na²²), urea, sodium thiocyanate, glucose, cellobiose, raffinose, and insulin. Briefly, we have found that all the macromolecules with molecular weight as large as or larger than 6000, the molecular weight of insulin, are retained almost quantitatively in the lymph ducts and are returned to the venous system by the thoracic duct. On the other hand, smaller molecules like sodium, urea, etc.

shuttle back and forth from lymph ducts and equilibrate with plasma very rapidly. Recently, we were fortunate in obtaining a dextran fraction of molecular weight of 2300. This substance appears to leave the lymphatic system as do the smaller substances. The limit of permeability thus seems to be somewhere between molecular weights of 2300 and 6000.

In these experiments, we always include radioactive albumin with the test substance and thus are able to assess any changes in permeability which may occur. In early experiments with urea, we infused high concentrations of urea (over 10%) in order to get a sufficiently high concentration for accurate analysis of our samples. Under these circumstances, there was a striking escape of albumin from the lymphatic system. Further experiments have shown that this phenomenon occurs only with concentrations of urea greater than 3 per cent (Fig. 6). Similar results showing increased leakage of albumin were obtained with the infusion of 25 ml of a solution containing 60 mg per cent sodium thiocyanate and 20 per cent radioactive albumin in saline. The mechanism of this apparently "toxic" effect of urea is being investigated as are the effects of high urea concentrations on blood capillary permeability.

Experiments with the isolated node preparation have given results which parallel those given above. As indicated, the small amount of albumin that finds its way to the plasma without going through the thoracic duct pathway evidently gets into plasma through capillaries of the node. The nature of this uptake has not been clarified. This preparation, although requiring patience and care in its use, should continue to be particularly useful in studies of uptake of other materials by nodes, and the functions of these nodes as part of the lymphatic circulation.

Much of the evidence relating to the absorption of substances by lymphatics has been concerned with absorption from the peritoneum. Here absorption occurs predominantly through those parts of the peritoneal surface of the diaphragm which overlie the lymphatic lacunes. To enter the lumen of a lymphatic lacune, materials must pass through a composite structure or "roof" consisting of *a*) a sheet of mesothelial cells, facing the peritoneal cavity and in continuity with the mesothelium of the rest of the peritoneum; *b*) a layer of connective tissue which forms a lattice of fibers; and *c*) an inner layer of endothelium in continuity with the endothelium in the walls and floor of the lacunae and ultimately with the endothelium of the efferent lymphatics.

The earliest and perhaps most tempting concept of

the mechanism by which macromolecules and particles entered lymphatics from the peritoneum was the postulation of openings in the endothelial walls. This concept was supported by the early work of von Recklinghausen (181a, 181b) and the presence or absence of "stigmata" and "stomata" have been debated for the last century. Cunningham (51a), in reviewing the subject in 1926, concluded, "In general, then, we may summarize the work which has been done on the mechanism involved in the absorption of particulate matter from the peritoneal cavity in the following way: The earlier work all tended to establish the concept of the presence of actual preformed physical openings between the peritoneal cavity and the diaphragmatic lymphatics. This idea was gradually eliminated and in its place the concept of potential physical openings between the walls was offered. In turn this hypothesis is being replaced by one which assumes that most, if not all, of the particulate material that is being absorbed from the peritoneal cavity passes directly through the cytoplasm of the mesothelial cells."

Lane Allen and his group have more recently revived the concept of potential physical openings. In experiments designed to test the upper limits of absorption, Allen (1b) injected intraperitoneally a variety of particles, yeast, mold, paraffin, and paraffin-asphalt spheres, and monitored diaphragmatic lymph for their recovery. He recovered spheres of mold of 10 μ , glass beads of 12.5 μ , and paraffin-asphalt spheres of up to 22.5 μ in diameter. He also recovered red blood cells in lymph at a level of up to 16 million per mm³. In later experiments, Allen & Weatherford (1c) injected polystyrene spheres with a range from chylomicron size up to 30 μ into the peritoneal cavities of mice, rats, and cats and recovered the particles from regional lymph nodes. The largest recovered spheres in the mouse were 16.8 μ in diameter, in the rat and cat, 24 μ . Allen (1b) presents his concept of diaphragmatic lymphatic absorption as follows: "As the diaphragm moves upward in expiration the lymphatic plexus expands and a relative negative pressure is established in the lymphatic lumen. At the same time the triple-layered membrane which separates the peritoneal cavity from lymphatic lumen is stretched. On either side of the fenestrations of the basement membrane the peritoneal mesothelium and lymphatic endothelium open, sometimes to form openings as great as 22.5 μ in diameter. Through these openings suspensions are 'sucked' into the lymphatic lumen. As the diaphragm contracts the tension on the lymphatic

wall is released, the openings close, and are no longer demonstrable by usual techniques, and compression of the plexus results in lymphatic flow."

The possible mechanisms of absorption of particles by the lymphatics of the diaphragm have been further clarified in a recent definitive study by French *et al.* (77a) using the light and electron microscopes. They point out that the mesothelial cells of the roofs differ from other cells at the peritoneal surface of the diaphragm in that they are more closely set, stain more darkly, and separate from each other more readily, particularly at the base of the intercellular junctions. The cells are supported by a lattice of coarse and fine fibers. In the meshes of this lattice, mesothelial and lymphatic endothelial cells are separated only by the basement membrane of the mesothelium which may be incomplete. The authors, using rabbits, injected India ink, thorium dioxide, and saccharated iron oxide intraperitoneally and found that the particles entered the intercellular spaces of the mesothelium and spread freely within the fibers of the fiber lattice. The particles appeared to pass through the mesothelium by a predominantly extracellular pathway and probably entered the lymphatic lumen through temporary channels formed by separation of endothelial cells at the intercellular junctions. These gaps formed by separation of mesothelial and endothelial cells also permit the passage of erythrocytes. The authors found that absorbed colloidal particles accumulated in the cytoplasm of mesothelial and lymphatic endothelial cells in the roofs, and their observations suggested that some of the absorbed material may be transported intracellularly through these two layers in cytoplasmic vesicles. In addition to uptake of particles by the endothelial cells in the roofs, cells in other sites in the diaphragm can also take up colloidal particles from the lumen of the lymphatic. In this respect, their results are similar to those of Odor (160a), who showed that particles of mercuric sulphide or Thorotrast were rapidly taken up from the peritoneal cavities of rats by mesothelial cells over the mesentery and diaphragm. On the other hand, Felix & Dalton (70a) found that melanin particles introduced intraperitoneally were actively ingested by free macrophages but not by mesothelial cells. These differences may be related to the difference in particle size or in the electron microscope preparations.

The evidence accumulated from recent studies thus suggests at least two possible pathways for the absorption of large particles (and erythrocytes) from the peritoneal cavity: 1) an extracellular pathway

consisting of gaps between mesothelial cells caused by pressure or, as suggested by Allen, by aspiration; 2) an intracellular pathway developed by infolding of the plasma membrane around particles and the subsequent pinching off of small pinocytic vesicles (13a). This vesicular mechanism may be concerned not only in transport from the exterior to the interior of the cell but also in transport through cells by a process termed cytopempsis (147a). The upper limit to the size of particles which can be absorbed through the extracellular route is probably determined by the size of the meshes in the connective tissue layer rather than by the potential openings between the mesothelial or endothelial cells. Smaller particles may travel through intercellular spaces in the roofs of the lacunes where the mesothelial cells separate from each other more readily than they do elsewhere. Evidence that small particles take an extracellular route through the lymphatic endothelium is perhaps not so convincing, but that particles can enter the interspace between lymphatic endothelial cells has been conclusively shown by Palay & Karlin (163a) in the central lacteal of an intestinal villus and by Casley-Smith & Florey (39a) in their study on lymphatics in ears of mice and guinea pigs, colons of rats, and diaphragms of mice. These authors suggest the possibility that lymphatic endothelial cells in general are less compactly joined than those in blood capillaries and may separate from each other more easily. The apparent absence of a continuous basement membrane to lymphatic endothelium, as discussed above, may possibly facilitate this separation of cells and be important in determining the permeability of lymphatic endothelium to macromolecules and particles traveling from without inward.

If we accept the fact that two possible pathways, intercellular and intracellular, are available for movement of substances through lymphatic membranes, their relative importance remains to be determined. How, too, are we to explain the striking difference between the ability of substances to enter and to leave lymphatic vessels? Cunningham reviewed the evidence available before 1926 and concluded that the main pathway of absorption is intracellular. Florey and his group, on the other hand, interpret their more recent results with the electron microscope as evidence of the possible greater importance of the intercellular pathway. They (77a) point out that there is no evidence that the greater permeability to colloidal particles shown by lymphatic endothelium when compared with blood capillary endothelium is explained by a greater frequency of cytoplasmic

vesicles. It is not too difficult, perhaps, to accept the point of view that the morphological basis of this relatively high permeability of lymphatic endothelium from without inward is related to cleavage at intercellular junctions and absence of a well-defined basement membrane. The available evidence from varied sources, although not always direct or definitive, is sufficient to suggest that mechanical factors, pressure and concentration gradients, elasticity of connective tissue, etc. (74a, 52a) may operate to move these substances from the interstitial space. Difficulty arises, however, in visualizing the same process as operating from within outward. Peters (171a) in 1935 appreciated this difficulty when he attempted to formulate a comprehensive theory of lymphatic absorption and raised the question as to how one could expect to hold water in a sieve by putting a valve at its mouth. Admittedly we still do not have sufficient information to provide an over-all sophisticated concept of permeability of lymphatic vessels. For the time being, it may therefore be wise to consider the following simple concept. We believe it to be consistent with the available evidence and to offer an explanation of the apparent one-way flow of materials into but not out of the lymphatics. Lacking evidence to the contrary, we may assume that the smallest terminal lymphatic capillaries are freely permeable to small and large molecules and particles moving in either direction through intercellular gaps. Compression of these vessels in any manner will force their contents in all directions. Some of the contents can, however, be forced centrally into larger vessels and ducts. The valves in these vessels will prevent backflow. Once the lymph reaches the larger vessels, it no longer loses its macromolecules and particles, since the walls of the larger vessels, as previously discussed, restrict molecules larger than molecular weight of approximately 2000 (at least in the dog).

This simple concept implies a relatively inept and inefficient system, a "leaky pump" system about which Peters complained. As Allen commented, however, a leaky pump will still pump, and as Drinker emphasized, the lymphatic system is, in the final analysis, a rather casual system. It does a reasonably good job under "normal" conditions. Its ineffectiveness becomes manifest chiefly under pathological situations. This aspect of the functions of the lymphatic system, its inadequacy in various pathological situations, will continue to merit careful study.

Summary of Venomotor Responses

insight which anyone may gain into the function of the arterial system by the simple registration of arterial blood pressure. As a consequence, very few physiologists or students of physiology have had any personal opportunity to make observations, other than the experiments of Harvey, which could be interpreted with confidence as manifestations of venous function. A major effort of this presentation, therefore, will be to stress the technical problems of obtaining reliable information concerning venous function and to review the degree to which presently imperfect methods have yielded interpretations that are in substantial agreement. This will lead us to some positive convictions about the functional role of the venous system in spite of many unresolved problems of methodology.

ANATOMICAL CONSIDERATIONS

Structure

IF ONE WERE TO CONSULT TEXTBOOKS for information on venous physiology, the impression would be gained that knowledge of this subject has not progressed since the classical observations of William Harvey. The error of this misconception should have been laid to rest by the excellent review of Gollwitzer-Meier (36), in 1932 and the comprehensive monograph of Franklin (32) published in 1937. The bibliography of this monograph, containing well over 1000 references, is scarcely compatible with the ignorance of the subject which is often reported. It is our impression that a major deterrent to appreciation of our knowledge of venous function stems from a failure to develop valid techniques that can be applied to the venous system with ease and technical accuracy, comparable to the

In general structural pattern, veins are composed of the same elements as are the arteries, but with some important quantitative differences. Surrounding the endothelial lining of the lumen is a network of elastic and collagenous fibers which form a clearly defined intima only in the larger veins; in the smaller veins there is very poor differentiation of the intimal layer. Encircling these intimal fibers is the muscular media, which remains essentially a layer of spirally arranged smooth muscle fibers without any major contribution of elastic fibers. This lack of a heavy elastic investment of the media constitutes the major structural difference between veins and arteries. Externally, the vessel is surrounded by the meshwork of elastic and col-

lagenous fibers constituting the adventitia. The adventitial layer becomes the major component of the wall of larger veins.

Another important difference between arteries and veins is in the structural relationships adjacent to the capillary bed. Whereas the arterial channels possess significant muscle terminating in conspicuous pre-capillary muscular elements at the arteriole-capillary junction, minute venules are devoid of muscle. Converging capillaries become surrounded with a collagenous network to form small venules which may not acquire a continuous muscular media until diameters of the order of 0.5 mm are reached. It must be clearly recognized on a purely structural basis, therefore, that there is no mechanism at the venous end of the capillaries capable of throttling blood flow in the way that blood flow may be controlled at the arteriolar end (85).

In describing these general structural features of veins, reference is specifically being omitted to some of the important variations which are found in the adaptations of specific venous beds to local problems. By way of illustration, suffice it to say that in the long veins of the extremities there is the development of a significant component of longitudinally oriented muscle capable of counteracting the gravitational stresses to which these vessels are subjected, while within the cranium venules develop to considerable size without the appearance of any muscular elements (61).

Vasa Venarum

Crucial to an understanding of some aspects of venous function is a recognition of the role of the vasa venarum, which constitute the normal route through which both nutrients and vasoactive substances reach the vein wall. Older literature on this topic has been reviewed by Ramsey (76). There is a dense network of minute vessels in the adventitia of the larger blood vessels which is particularly conspicuous in veins. Although some techniques have failed to reveal a penetration of the capillary plexus into the media, adequate methods have succeeded in demonstrating a profuse capillary bed extending almost to the intima (67). In addition to the capillary plexus, there is clear evidence of an accessory duct system, presumably lymphatic in nature, which is distributed through the adventitia and media.

It must be emphasized, however, that the vasa venarum do not penetrate the intimal layer and drain through the local endothelium. Venous drainage from

the capillary plexus returns to venules running along the superficial layer of the adventitia, and eventually drains into either an entirely different vein or a remote site of the same vein. O'Neill has pointed out that this relationship assures that local obstruction in a venous segment will not block the flow in the vasa venarum, nor can local pockets of high intraluminal pressure induce backflow in the vasa venarum of the venous wall. A similar relationship exists in the arteries.

Functional confirmation of the anatomical relationships described above has been provided by O'Neill (67). Extensive damage to the intima followed stripping the tissues surrounding the vein so as to interrupt the vasa venarum, even though blood flow was maintained through the lumen of the vein. This indicates that oxygen and nutrients do not pass in significant amounts from the lumen into the surrounding tissue of the vein wall, and that the venous wall is clearly dependent upon the vasa venarum. Comparable evidence may be observed with drugs. Minimal response to vasoactive agents can be demonstrated when the drug flows through the lumen of the veins, while very effective vascular responses result when the drug is applied systemically or topically so that it may reach the media from the adventitial side.

This anatomical arrangement seriously handicaps the study of functional changes in the vasa venarum. In the case of arteries, the vascular wall is supplied not only by vessels penetrating from the adventitial side, but also by some vasa vasorum interna which penetrate the wall directly from the lumen. Smith (83, 84) has taken advantage of this relationship to use the amount of leakage, in response to internal pressure changes, from the surface of an excised arterial segment as a measure of vasa vasorum flow. A similar technique would not be applicable to veins. In the study of diseased veins, a further complication arises in that the anatomical pattern changes qualitatively as well as quantitatively. The early inflammatory phase of vascular disease stimulates a dense invasion of vascular elements into the wall of the vessel with the creation of venous channels that penetrate the intima directly into the lumen of the vessel, creating vasa venarum which have no counterpart in normal veins.

Innervation

Veins are copiously supplied with nerves which Thompson (86) demonstrated, in 1893, to be capable of producing constriction of the vein. Bayliss & Starling (8) confirmed the existence of neurogenic veno-

constrictor mechanisms and, on the basis of changes in arterial and venous pressure following spinal transection, inferred that the nervous system must be of importance in maintaining venous tone. Donegan (19) studied this innervation in greater detail and established that it was sympathetic in nature. As with other sympathetic pathways, localization is rather gross, with a given vein segment responding to stimulation from several adjacent spinal segments. There is now clear evidence of a tonic constrictor activity of this sympathetic innervation, since venous dilation occurs with sympathectomy (9, 54) or with sympatholytic drugs. This adrenergic sympathetic influence appears to be purely constrictor without any dilator component (62). Conversely, there appears to be no evidence of parasympathetic innervation of veins. Although pharmacological doses of cholinergic drugs may influence venous musculature, neither parasympathetic stimulation nor atropinization have any effect on venous tone (31). Even in such a highly specialized vascular function as penile erection, parasympathetic control appears to be restricted to the arterial side of the circulation, with the veins playing a purely passive role (47).

Venous Valves

A unique feature of the venous system is the presence of venous valves. The dramatic simplicity with which the nature of this valve action can be demonstrated in the veins on the dorsum of the hand remains one of the classical observations of physiology. Clinically, the role of the venous valves in the lower extremities have received particular attention. The superficial veins of the leg, lacking protection from surrounding muscle, are often subjected to prolonged hydrostatic loads. This excessive distension of the vessels may eventuate in valvular incompetence. The consequences of this valvular incompetence and its relation to venous varicosities and varicose ulcers has been analyzed extensively in the literature on peripheral vascular surgery. (See Burch, Chapter 36.)

This focusing of attention on the venous valves of the extremities has distorted an appreciation of the significance of valves in the venous system as a whole. For example, a widely prevalent notion is typified by the following statement from a leading textbook of histology (46): "Valves are especially abundant in the veins of the extremities and they are generally absent from the veins of the thorax and abdomen." In actual fact, valves or valve-like structures have been reported in most segments of the venous system,

although generalizations are difficult because of the marked species variation which has been reported (29). The distinguishing feature of the valves in the extremities is not their presence but the degree of competence which they exhibit; venous valves in areas not confronted with severe hydrostatic strains are usually more rudimentary and therefore less easily demonstrated.

An example of the latter type of valvular structure in abdominal veins is illustrated in figure 1 from a preparation made by Dr. Darrell Davis. This is a photograph of a plastic cast of venous vessels obtained by retrograde injection of a segment of dog intestine. Numerous valve impressions are clearly identifiable on this preparation. Just before each point of junction, most of the tributaries contain a valve. In every instance the injection mass terminates with a bilobed indentation which clearly represents a valve. Blood traversing this venous bed must pass through a series of valves before gaining access to the portal vein.

It should be appreciated that figure 1 also demonstrates a relative incompetency of these valves, in that the injection mass has readily passed beyond a number of the valves. Accordingly, in spite of the profusion of valves in this bed, it is reasonably easy to reverse the flow of blood in the intestine. If artery and vein of a loop of dog intestine are sectioned and a circuit re-established whereby the intestinal vein is connected to an arterial supply and the artery led out to a route of venous drainage, a substantial retrograde flow is observed for several minutes, eventually becoming reduced as massive edema develops from the abnormal capillary pressure relationships. Measurement of pressure gradients and flow demonstrates that retrograde flow encounters a resistance of three to ten times the vascular resistance to forward flow during

FIG. 1. Plastic cast of mesenteric veins of a dog demonstrating multiple valves. (Preparation made by Dr. Darrell Davis.)

the early phase of the reversal. While a good part of this resistance is undoubtedly attributable to the valves, the situation contrasts with that observed in healthy veins in the extremities where valves present infinite resistance to retrograde flow until very high pressures are reached.

The functional contribution of venous valves should be clearly defined. In the idealized circulatory scheme with continuous venous flow, the valves must necessarily remain open and hence make no functional contribution. With intermittency of flow, due, for example, to intermittency of flow in the peripheral bed, the valves would tend to close during the intervals of flow cessation. Nevertheless, we must reject the view that this "breaking up" of the venous column into segments relieves the dependent parts from the hydrostatic load of a continuous fluid column. The hydrostatic gradient is inherent in the hydraulics of the system; energetically the valves cannot contribute to the need for adequate pressure energy to overcome the hydrostatic barrier between dependent parts and the heart. In the system as a whole, intermittent flow must preserve the same mean pressure gradient as is required of continuous flow.

Valves make their functional contribution by translating extramurally applied forces into flow energy. When an external force compresses a fluid-filled vessel, local intramural pressure will rise and tend to drive the blood in both directions from the point of compression. The actual flow which will occur in the two possible directions will be a function of the pressure gradients and resistances in the alternate directions. The resistance to retrograde flow toward the capillary bed is far higher than the resistance to forward flow toward the heart, and the pressure gradient, which normally favors central return, would very strongly favor central flow the moment the retrograde flow combined with continuing capillary drainage to build up peripheral venous pressure. Thus it should be appreciated that a "milking" action of intermittent venous compression will effectively propel blood toward the heart even in the complete absence of valves. Valves, however, can greatly increase the efficiency of this process by producing an almost immediate rise of retrograde resistance to infinity.

The importance of this process is most clearly demonstrated by the dramatic relief from orthostatic hypotension which is produced by movements of the legs and their associated compressing forces on the leg veins. Walking movements are so effective in propelling flow up the venous channels that they can

restore adequate venous return to the heart even when vasomotor tone has been completely abolished by sympatholytic drugs (71). Direct measurements have demonstrated that the sequential compression of venous segments during walking milks blood up the legs efficiently enough to reduce the pressure in the uncompressed veins of the ankle to less than one quarter of the hydrostatic gradient from the ankle to the heart (74). There is no question that such extravascular forces constitute a significant "booster pump" (49) for maintaining the circulation. The idea championed by Henderson (48), that muscular activity acting in conjunction with the venous valves was the primary "venopressor" mechanism, should therefore not be dismissed lightly, even though this mechanism does not appear to play quite such a comprehensive role in maintaining venous return as Henderson claimed (90).

Venous Capacity

Because of the relatively large caliber of veins, and also the conspicuous venous sinusoids which occur in some organs, it is commonly supposed that the capacitative function of the vascular bed resides dominantly in the venous system. The full functional significance of this concept will be developed in the next chapter. Our concern at the moment is confined to examining the evidence underlying this basic assumption.

Widely quoted data in support of this venous reservoir concept are those published by Green (37) calculated from an analysis of the intestinal vascular bed of the dog reported by Mall. These data picture some 70 per cent of the vascular capacity to reside in the venous system with 62 per cent in veins greater than 1 mm in diameter. Landis & Hortenstine (58) carried out a very similar calculation based upon the intestinal data of Schleiser, which yielded a value of 75 per cent of the vascular volume within the venous system, 50 per cent of the total being found in veins greater than 1 mm in diameter. The Landis calculation did not include the venae cavae, inclusion of which would have increased the percentage of volume in the large veins.

It is distressing, however, when one realizes how little direct evidence there is to support these estimates. By measuring the mean transit time for dye passage between the femoral vein and the right atrium, Milnor & Bertrand (65) were able to calculate a volume between these two sites which averaged 18 per cent of the total blood volume. Since the inferior vena caval system is a notoriously poor mixing

chamber, one would expect the true volume to exceed that calculated by this method. This study therefore represents some substantial support for the idea that large veins represent a significant contribution to the total vascular capacity. On the other hand, Knisely and associates (57) have challenged the conventional point of view with some data obtained from plastic injections of whole rats. Using a plastic free of particulate matter which flowed freely through the circulation when initially injected, they obtained casts of the entire vascular bed. When these casts were fragmented, and the fragments sorted according to caliber, over 80 per cent of the plastic was found to be contained in vessels with a diameter of less than $200\ \mu$ and only 12 per cent in vessels larger than $700\ \mu$. This study suffers from the fact that veins are collapsible, and it is not at all clear that their method would have preserved a normal degree of filling of the venous system. Nevertheless, such an extreme discrepancy between the relative contribution of large vessels and small vessels to total vascular capacity clearly challenges the point of view that is usually held. The burden of proof has been returned to the proponents of the venous reservoir concept to offer some more substantial documentation of their hypothesis.

Apart from the question of total capacity, however, there is much better support for the thesis that the venous division, together with the lesser circulation, is the most variable capacity of the vascular bed. One very simple observation leading to such an inference is the minimal change in pressure produced by an injection into the venous system as compared to the pressure change produced by an injection of an equal volume at the same rate into the arterial system. More direct evidence on this point was presented by Greenfield & Paterson (39), who compared volume changes in the forearm produced by venous obstruction to the volume changes produced by a negative pressure applied to the whole arm. In the former instance, the increase in transmural vascular pressure would be essentially confined to the venous side; in the suction experiment, the transmural pressure of all vessels should be increased equally. Yet venous occlusion provided 85 per cent of the volume increase observed when suction was applied to the whole arm. A similar experiment was reported by Capps (16). Such data, together with venous distensibility characteristics to be discussed later, justify reasonable confidence in the hypothesis that the venous system plays an important role in contributing a reservoir of variable capacity to the vascular system.

PHYSIOLOGICAL CHARACTERISTICS OF VEINS

Principles of Venous Hemodynamics

The most frequent measurement made of the venous system is the venous pressure. For the purposes of our interests however, venous pressure is of relatively little meaning. As competently reviewed by Landis & Hortenstine (58), venous pressure can have profound influence on capillary dynamics and the transudation of fluid across the capillary endothelium. Central venous pressure plays a key role in cardiac filling and the control of cardiac output. For reasons that will be developed shortly, however, venous pressures tell very little about the venous system itself. Indeed, it can be fairly stated that venous pressure measurements in themselves are just as unimportant to the physiologist interested in the venous system as they are important to the physiologist interested in the arterial system.

Before specifically considering the principles of hemodynamics underlying this statement, a word of emphasis should be given in reference to the implication of the studies of Pappenheimer (69, 70) on the capillary bed. He has lucidly argued that, under steady-state conditions, the mean capillary pressure must be in equilibrium with the effective osmotic pressure of the plasma proteins, excluding lymph flow which at best is a small fraction of total blood flow. Since central venous pressure shows relatively small variations under most conditions, this indicates a relatively constant pressure gradient from capillaries to the central veins. Furthermore, large changes in blood flow may occur without significant alterations in either plasma protein concentration or central venous pressure, yielding the apparent paradox of blood flow that varies widely in spite of a fixed pressure gradient. A corollary to this is that the venous smooth musculature cannot effectively control blood flow by imposing a variable resistance in the venous portion of the circulation. The role of the venous musculature must therefore be confined to producing capacity changes in the system. These capacity changes can indirectly influence blood flow only insofar as more effective venous return increases cardiac output, or higher mean circulatory pressures increase capillary transudation.

If some of the preceding statements appear to be in conflict with irrefutable principles of fluid dynamics, the reader must be reminded that the venous system is a collapsible system and is therefore not governed by the usual principles of fluid dynamics in

cylindrical tubes. The phenomenon of venous collapse was inherent in the classical observations of Harvey. It has remained a commonplace observation in the use of the height above the heart at which superficial veins collapse as a clinical estimate of central venous pressure. Yet the hemodynamic significance of venous collapse has been all too rarely appreciated.

First, it is important to note that "collapse" of veins is not an all-or-none characteristic. Complete collapse of the vein with obliteration of its lumen represents an obstruction to blood flow which can only exist on a transient basis. The collapse phenomenon relates to the fact that the vein wall is not structurally self-supporting. Energy is required to push the vein walls out into a cylindrical configuration. Any time that the intraluminal pressure becomes equal to or less than the extravascular pressure, the venous walls will tend to approximate each other in an ellipsoidal cross section (73).

This is best visualized by examining veins above heart level. Hydrostatic forces will act to drain blood from these veins and create a negative intraluminal pressure. In addition, finite tissue pressures always produce some degree of positive extravascular compression. In the absence of blood flow, such a vessel would remain completely collapsed. To preserve flow in such a segment, intraluminal pressure must be raised until it slightly exceeds the extravascular pressure so as to open the collapsed vein. Intraluminal pressure must further be elevated enough above extravascular pressure to provide the necessary pressure head to produce forward flow against the resistance it confronts. However, since a slightly positive transmural pressure will widen the collapsed lumen and produce a marked fall in resistance, very little pressure gradient is required to produce flow. Therefore, the pressure measured in veins that are above heart level will be essentially the same as the extravascular tissue pressure, as originally emphasized by Holt (51, 52, 80). It follows that such pressures have no hemodynamic significance in the usual sense of gradients along the vascular circuit, and they are in no way specifically related to constriction or dilation of the veins.

A more rigorous statement of this relationship has been clearly set forth in the exposition by Brecher (11). The classical formulation of the Poiseuille law for cylindrical tubes:

$$\text{resistance} \propto \text{radius}^4$$

must be modified for collapsible tubes to the more

complex expression:

$$R \propto \frac{2a^3b^3}{a^2 + b^2}$$

in which R is resistance and a and b are the major and minor axes of the ellipse. It should be noted that in a cylinder where $a = b$, the second expression reduces to the first. As an operational tool, this formulation of resistance relationships is rarely of practical value to the physiologist because the desired dimensions are not accessible. Nevertheless, from a theoretical standpoint it defines the fact that resistance to flow will increase markedly as the vessel progressively collapses to a flattened ellipse.

The full import of this collapsibility resides in the consequences it has upon the significant variables determining blood flow. In a system of cylindrical tubes, as represented by the arterial system, pressure is normally maintained at homeostatic levels in the arterial reservoir and, for any given vascular bed, blood flow is controlled by resistance changes through the activity of the vascular smooth muscle in the arterial supply to that bed. To emphasize this point, one might consider the pressure as essentially constant (P_a) under a given situation and the significant variables of flow (\dot{Q}) and resistance (R_a) expressed as:

$$\dot{Q} = \frac{1}{R_a} \times P_a$$

In contrast, in any local venous bed, the flow is obligate since in a steady state the veins must transport the volume of blood delivered by arterial inflow. Flow may therefore be considered constant and in any venous segment resistance is controlled by the local pressure (P_v) which, as outlined above, must represent a small increment over the extravascular pressure:

$$R_v = \frac{1}{P_v} \times \dot{Q}$$

Stated descriptively, in the venous system operating under a state of partial collapse, local venous pressure determines the cross section of the ellipse and thereby adjusts resistance to accommodate the volume of flow presented to the system.

Extending this analysis further, in the arterial system an increase in the reference pressure (P_a) will immediately lead to an equivalent increase in the flow (neglecting factors of vessel elasticity and autoregulation). In the venous system, an increase in the reference flow (\dot{Q}) will tend to increase pressures slightly along the venous route. This will widen the

FIG. 2. Hemodynamic relationships in the venous bed, adapted from Holt (51) and Brecher (10). Solid lines indicate relationships without compensation; dashed lines indicate relationships with compensation in arterial inflow resistance. "O" pressure refers to the hydrostatic level of the peripheral vein.

ellipse and lower resistance so as to support an increased flow without change in the total pressure gradient from capillaries to heart.

The key relationships in this pattern of venous hemodynamics are illustrated in figure 2. For veins above heart level, the hydrostatic column of blood descending toward the heart creates a potentially subatmospheric intraluminal pressure tending to suck the walls of the vein in to cause collapse. Typically, this phenomenon will be most manifest at the point just before the venous channel enters the thoracic cavity, since in this region the negative intrathoracic pressure combines with the hydrostatic forces to aspirate blood from the veins. At the left of figure 2, therefore, central venous pressure is indicated as below atmospheric pressure; yet peripheral venous pressure is maintained at a definite positive value. Since under these conditions there is a significant pressure gradient, an appreciable resistance exists between the peripheral and the central veins. This resistance is created by the state of partial collapse near the central end of the channel. As the central

venous pressure rises toward atmospheric pressure, the aspiration effect causing collapse becomes progressively less, so that the resistance to flow progressively lowers. Peripheral pressure, however, remains unchanged. As the central venous pressure rises above atmospheric pressure, there continues to be an interval when the intravascular pressure remains below the extravascular pressure because of the existence of a positive tissue pressure in the area surrounding the veins.

As the central venous pressure reaches the value of the extravascular tissue pressure, a dramatic alteration occurs. The intraluminal pressure will now be sufficient to prevent collapse of the vein. As a consequence, the venous channel is distended and the more typical Poiseuille relationship pertains. Neglecting the minor influence of elastic distension of the veins, resistance between the peripheral and central veins remains constant at a relatively low value, and correspondingly a relatively constant small pressure difference exists between the peripheral and the central veins. Peripheral venous pressure will therefore rise almost parallel with central venous pressure.

It is to be emphasized that at all central pressures below the level of tissue pressure, the peripheral venous pressure remains at essentially the same level as the tissue pressure. Assuming there are no changes in arterial pressure or resistance factors, a constant peripheral venous pressure dictates a constant capillary blood flow. It is to be noted, therefore, that flow remains constant in spite of the significant changes in pressure gradient and resistance along the venous route. Once the central venous pressure rises above the tissue pressure, venous congestion occurs with a rise in peripheral venous pressure and a corresponding reduction in the arteriovenous pressure gradient. This will have some influence in reducing flow through the system unless compensated by other changes. In actual fact, a large rise in peripheral venous pressure reduces peripheral blood flow so that vasodilator metabolites accumulate in the tissues. The resulting compensatory dilation of the arterial inflow channels will counteract the elevation of peripheral venous pressure and maintain constant flow, as illustrated in the dashed lines of figure 2.

Any factors leading to a change in the extravascular tissue pressure will produce an equivalent change in the peripheral venous pressure, a corresponding alteration in resistance, and a shift of the point of inflection of the curves. Flow, however, will remain unchanged.

Students of the venous system must wrestle with

this concept until they come to recognize its profound implications. While the application of Poiseuille's law to collapsible tubes requires only minor modifications in arithmetic, the degree of determinacy of the respective variables is radically different. For example, there is a vast body of older literature which demonstrates that venous pressure is not altered by a host of physiological factors known to alter the regulation of the cardiovascular system. The conclusion of these authors, that the venous system therefore played no part in cardiovascular regulation, may be a significant reason why most textbooks are devoid of positive statements in regard to venomotor mechanisms. What these experiments actually proved was that the various experimental maneuvers had no effect on the extravascular tissue pressure which is the major determinant of venous pressure; such measurements are completely meaningless in reference to venous tone.

It would be a serious error, moreover, to regard the collapsibility of veins as a structural defect in the system which serves no better purpose than to complicate the understanding of venous hemodynamics. Since the venous system operates in the same pressure ranges as the gravitational forces and tissue pressures to which it is exposed, drastic disturbances would result if veins were rigid tubes. Consider, for example, an individual turning a handspring. If veins were rigid, there would be drastic surges in venous blood flow and chaotic alterations in venous return to the heart. More conventional running and jumping movements would seriously tax the homeostatic adjustment of a low pressure system of cylindrical tubes. The collapse mechanism serves to check such hydrostatic shifts of venous blood. As soon as pressure in the veins becomes reduced to tissue pressure levels, collapse occurs to throttle flow and maintain the peripheral bed at more nearly normal functional levels.

Duomarco and associates (22-24) have extended this concept of venous hemodynamics to claim that the design of a collapsible venous system guarantees that extravascular factors capable of altering pressure relationships can have no influence on venous flow. Duomarco's enthusiasm for the teleological magnificence of such a scheme apparently exceeds the actual facts. It must be appreciated that, with normal blood volume, a significant fraction of the venous bed is distended so that it does behave as a system of cylindrical tubes. This will hold for most of the extrathoracic veins which are below heart level and which are not in regions subjected to significant extravascular compression. Furthermore, the work

of Brecher (10) has established that phasic pressure changes are capable of producing phasic changes in flow during the intervals when geometric adjustments in the degree of collapse are taking place. Such phasic pressure changes are conspicuous in intra-thoracic and intra-abdominal veins in association with respiration, and also seem to be a characteristic manifestation of venous vasomotion in the small peripheral veins (44).

An additional word of caution should be appended to emphasize that there are some important exceptions to generalizations as to the collapsibility of veins. This is particularly true of venous structures that are bound by connective tissue to rigid skeletal elements which prevent their collapse, such as the sinuses of the dura mater and the vertebral venous sinuses. In these vessels, gravitational or respiratory forces may lower the intraluminal pressure to values significantly below the pressure existing on the outside of the vessel. A clinical consequence is the danger of air aspiration into the vascular system if these vessels are opened to the atmosphere during surgical procedures or by accidental trauma. A similar problem exists to a lesser degree at the point where veins enter the chest. The thyroid surgeon is well aware that veins near the base of the neck have sufficient connective tissue attachments so that traction may pull open an incised vein that has not been securely ligated, and acroembolism result when inspiratory pressure changes lower the central venous pressure below atmospheric pressure.

To qualify generalizations about venous collapse, however, should not obscure the importance of this phenomenon in venous function as a whole. Any approach to the venous circulation which neglects the collapsibility of veins will lead to serious distortions of the hemodynamic factors which control the flow of venous blood.

Venous Distensibility

In view of the collapsible nature of veins, a vein segment will empty freely from cut ends, the vessel will flatten and all blood will leave the lumen except for a minute amount retained within the folds on opposite sides of the vessel. If fluid is now added to this collapsed vessel, two theoretically distinct processes will occur. The first phase will be "filling," during which the geometry of the vessel wall is restored to the cylindrical shape without increasing in circumference. The succeeding phase will repre-

sent elastic distension of the vein segment through increase in its circumference and length.

The inference sometimes encountered, however, that the vein remains at "zero" pressure until it is "filled" is quite unrealistic. Some finite pressure is required to restore the wall to its cylindrical shape. For veins in situ, filling the vein must also overcome tissue pressure, and local tissue pressure will itself be augmented by the swelling of the vein. Finally, as fluid starts to fill the vein, hydrostatic pressures will be created unless the vein is perfectly horizontal. Consequently, if one records intraluminal pressure accurately while fluid is progressively added to an empty vein in vivo, pressure starts to rise almost immediately and does not show any recognizable inflection when the vein is "filled" (fig. 3).

The pressure-volume curves obtained from venous segments, or the tension-length curves obtained from strips or rings, are most commonly described as curvilinear with considerable convexity toward the length or volume axis. Clark (17) was the first to recognize that these two types of measurement must be related by the Laplacian relationship whereby in a cylindrical tube, wall tension (T) increases as a

function of pressure (P) and radius (R):

$$T = P \times R$$

It follows that at small radii, relatively less wall tension is created by a given pressure increment than at large radii. The pressure-volume curve shows correspondingly less curvature than the tension-length curve.

Figure 3 illustrates the volume change due to radial distension as contrasted with the volume increase due to elongation. It is apparent that most of the volume increment results from radial distension within the physiological range of venous pressures. It is only above pressures of 30 to 40 cm H₂O that radial distension becomes restricted to the relatively low degree of distensibility which is characteristic of longitudinal distension. A further important characteristic of the longitudinal distension of veins, that is not shown by such data, is the spiral twist which veins exhibit when they are subject to sufficient pressure to produce significant longitudinal stretch. Presumably because of the spiral structures within the vein wall, there is a definite rotation of one end of the vein in respect to the other end as the vein lengthens. Teleologically,

it appears reasonable to suggest that this spiral twist of a distended vein may be of importance in relieving kinking of the veins when the tissue is mechanically distorted.

Quite a different curve of vascular distensibility was presented by MacWilliam (60) as shown in figure 4. He took the precaution to collect fresh tissues and observe their behavior carefully during the postmortem period. Shortly after a segment of living vessel was excised, it developed marked spasm. This spasm persisted for many hours if the tissue was kept cool. In this contracted condition a stretch curve, such as that shown in the lower half of the figure, was observed. When the state of contraction was eliminated by warming the vessel, a more conventional stretch curve was obtained as shown in the upper portion of the figure. The marked sigmoid curve observed originally has now been replaced by a simple bow convex to the length axis. MacWilliam interpreted the lower curve as a manifestation of the resistance to stretch of the smooth muscle, which gradually gave way as tension increased until eventually stretch was restricted by the elastic and fibrous tissue of the vessel wall. The upper curve lacked this muscle component, and therefore revealed the simpler manifestation of elastic tissue distension. This change in the distensibility pattern was quite characteristic of arteries; it was not so evident in the veins studied by MacWilliam.

FIG. 4. Stepwise loading of a ring of artery which in the lower section was in a contracted state from preservation in the cold. In the upper tracing the identical loading sequence was repeated after the vessel had been dilated by warming. [From MacWilliam (60).]

FIG. 5. Distensibility patterns recorded from veins in vivo (4).

A majority of investigators have considered this spasm of the excised vessel as a postmortem artifact, and many describe techniques employed to remove this state of spasm in the tissue before carrying out studies of its elastic behavior. The potential significance of this observation of MacWilliam therefore lay dormant for many years, until Capps (16) observed the same type of curves in plethysmographic recordings obtained from the human arm. The sigmoid type of distensibility curve was associated with constricted veins, and the smooth bow was associated with dilated veins.

More recently the significance of this distensibility pattern of constricted vessels and of dilated vessels has been analyzed by the author (2-4, 78). There is now ample evidence that these distensibility patterns are exhibited by living veins in vivo (fig. 5) and, as will be discussed later, their analysis can serve as a useful index to the state of contraction of the veins.

Another feature of vascular distensibility, which has been recognized since the time of Roy (79), is the marked time dependency in elastic behavior (1). This has been variously identified as "elastic after-action," "elastic hysteresis," "delayed compliance," or probably more properly by the physical phenomena of "stress relaxation," in which pressure dissipates following sudden distension to a constant volume, and "creep," in which volume slowly increases after sudden distension by a constant pressure. With a continuous cycle of injection and withdrawal of fluid, this characteristic manifests itself as a wide loop of disparity between the pressure-volume relationships observed on injection and the pressure-volume relationships found on withdrawal (figs. 6 and 7). To a degree, the width of this loop demonstrates time dependency, in that it tends to become

FIG. 6. Continuous injection (upper dashed line) and withdrawal (lower dashed line) of blood into mesenteric veins of a dog at the rate of $37.5 \text{ cm}^3/\text{min}$, compared with an injection performed at the same rate but interrupted at three points for intervals of 10 sec. Note that the stress relaxation, demonstrated by the loop in the continuous curve, is significantly greater as the higher pressures are reached in the interrupted curve (38).

narrower at very fast and very slow rates of injection, being widest when the rate of injection and withdrawal permits the greatest degree of stress relaxation to occur between the injection phase and the withdrawal phase. In addition to this simple visco-elastic type of behavior, moreover, veins also exhibit plastic properties, in that the stress relaxation is minimal at very low pressures, and becomes disproportionately exaggerated at higher pressures, as indicated in figure 6. It appears that certain "yield pressures" are required to produce the transformation which gives rise to the stress relaxation.

The complex problem of the exact basis for these properties of blood vessels (78) is beyond our scope here, but it should be appreciated that these characteristics have two implications of importance in evaluating distensibility determinations. First, pressure-volume data obtained from veins are strongly influenced by the exact conditions of venous distension, and data are never rigorously comparable unless identical rates and magnitudes of distension are used. Unfortunately this requirement has often been overlooked, and a large bulk of published data must be questioned because of failure to impose exactly defined and standardized procedures for obtaining distensibility determinations.

A second important facet to this problem is the effect of a repeated stretch. As is to be expected of a tissue showing a significant stress relaxation, a second stretch curve differs greatly from an initial stretch. This characteristic is most prominent in the constricted vein, in which the sigmoid pattern of distensibility characteristic of an initial stretch is obliterated in succeeding stretches (5). Studies have

shown that 20 to 30 min are required for a complete restoration of the initial distensibility pattern following an initial stretch of the tissue. Related to this is the fact that the distensibility pattern observed on release of stretch of a constricted vessel is identical to the pattern observed with the release of stretch of a dilated vessel (fig. 7). Stretch of the tissue appears to "pull out" the muscle so that it no longer contributes to the distensibility characteristics of the tissue until considerable time has elapsed for this muscular influence to become restored. This dictates that not only must precise distensibility data be gathered with rigorously defined rates of stretch, but also the intervals between stretches must be rigidly controlled.

A further problem should be mentioned to which there is at present no satisfactory answer. Many have argued that distensibility data have no absolute meaning until they are converted into terms of a quantitative modulus of elasticity which relates the tension-length or pressure-volume increments to the initial length or volume parameters of the tissue. There are certain practical difficulties which interfere with accomplishing this objective. With *in vivo* measurements, accurate estimates of initial dimensions are extremely difficult to obtain even when pressure and volume increments are readily measured. Furthermore, inherent to the calculation of an elasticity modulus is the assumption of homogeneity of the tissue, and some investigators have questioned whether a meaningful modulus can be calculated from tissue

FIG. 7. Injection and withdrawal of blood at the rate of $50 \text{ cm}^3/\text{min}$ into mesenteric veins of a dog constricted by neo-synephrine (NEO) and subsequently dilated by adenylic acid (A.A.). The injection curves demonstrate the characteristic convexity and concavity patterns portrayed in fig. 5, but the withdrawal curves were perfectly superimposed.

dimensions which include many components in addition to those controlling the elasticity of the structure. As a consequence, most of the data in the literature are presented as pressure-volume increments of a system, the total volume of which remains undefined.

A significant point in this connection relates to the interpretation of the sigmoid distensibility pattern of the constricted vein (fig. 5). If we accept the interpretation given that stretch acts to "pull out" the muscle so that distensibility is eventually restricted by the elastic and fibrous tissue, it follows that at extreme degrees of stretch both constricted and dilated tissues should possess the same length at the same tension. The record in figure 4 accords with this as a first approximation, although actual measurements reveal a minor discrepancy in the recorded lengths. *In vivo* measurements, by direct injection (2) and by indirect plethysmographic studies (39), also suggest that with maximum distension the volumes of constricted and dilated veins converge. Burton (15), however, has challenged this interpretation, and offered evidence that constricted vessels retain a smaller caliber than dilated vessels regardless of how much they are stretched. Recent studies on isolated tissues, the dimensions of which can be accurately recorded, have thrown additional light on this problem (77). There appears to be no fixed correlation between the unstretched length of a tissue and the pattern of its distensibility curve. Although repeated stretch of a constricted tissue can eliminate the sigmoid distensibility pattern and yield a convex curve indistinguishable from that of a dilated tissue, this stretch does not erase the shorter unstretched length of the constricted tissue. In other words, the "pulling out" of the muscle by stretching a constricted tissue does not transform it into a dilated tissue. An ultimate resolution of the nature of these changes must await a fundamental understanding of tissue elasticity, very probably extending to the molecular level (78). Until that understanding is at hand, we must be cautious not to oversimplify the distensibility characteristics of veins.

Nature of Venous Constriction

Most references to venous constriction visualize a uniform increase in tonic activity of the muscle so as to reduce the caliber of the vessel, without further definition of the process or processes involved. There is evidence, however, that in addition to increases in venous tone there are more extreme and more sus-

tained forms of venous constriction which justify the designation of "venospasms." The latter may be localized or may involve more extensive segments of the venous bed.

The local spasm which frequently is induced by the trauma of venipuncture is a commonplace observation to both the experimentalist and the clinician. Since this response cannot be abolished by denervation, it must include a significant local mechanism in its genesis. Inversely related to this traumatic venous spasm may be the localized dilation which can be evoked by tapping a vein (33). There are also occasional reports of localized rings of constriction in a venous bed under conditions where there appears to have been uniform stimulation of the bed. Such irregular segments of constriction are shown in figure 8, which illustrates intestinal veins following the intra-arterial administration of levarterenol. In extreme cases, this pattern of reactivity may distort the vein so that it resembles a string of sausages, with rings of constriction separating distended segments.

There are two plausible lines of explanation for this type of segmental venospasm. One could relate to anatomical or functional differentiation of different regions of the vein wall in which certain segments are more sensitive to stimulation or more powerful in the magnitude of response that they can develop. Another possible explanation relates to the Laplacian phenomenon discussed earlier (17). The moment one area of vein reduces its caliber slightly more than an adjacent area, its mechanical ability to compress the lumen increases, even though the tangential tension

FIG. 8. Segment of dog mesentery following the intra-arterial injection of levarterenol, demonstrating the irregular distribution of constriction sometimes exhibited by veins.

in the wall remains the same. Much as in the classical soap bubble or balloon experiments, the smaller element will force its contents into the larger element. Although more information is needed to clarify this phenomenon, it appears worthy of mention because of its possible relationship to certain aspects of venous varicosities.

The phenomenon of more generalized venospasm still remains largely unsolved. An important characteristic is that this type of venospasm involves a significant neurogenic spread which influences both arterial and venous elements so as to throttle blood flow through the entire bed. In experimental venous thrombosis, for example, the reduction in blood flow to an extremity far exceeds anything attributable to the local mechanical block, apparently due to reflex constriction involving all vascular elements of the limb (66). A suggestion as to the factors responsible for the maintenance of venospasm under these conditions is found in the observations of Donegan (19). In the presence of good blood flow and well-filled veins, nerve stimulation evoked a brief phasic constriction of veins which resembled the typical response of smooth muscle to nerve stimulation. When a vein was poorly filled, on the other hand, little detectable response was observed unless intense stimulation was given, whereupon the vein constricted strongly and remained constricted for a period of 6 to 12 min. It is therefore evident that venous distension has an influence on the ability of the venous musculature to contract maximally, which is quite compatible with the influence of venoconstriction on venous distensibility, as previously discussed. It leads us to the conclusion that venospasm is a phenomenon produced when dynamic conditions are such as to displace the vein over to the bottom of the sigmoid distensibility curve (fig. 5). It is still far from clear, nevertheless, as to just what types of conditions of stimulation can evoke such a venospasm.

ASSESSMENT OF VENOMOTOR ACTIVITY

In Vitro Studies

The most direct method for studying venous smooth musculature is to measure the reactivity of rings of venous tissue in vitro. Rings, circumferential strips, or spirally cut strips (59) are most suitable for such studies; longitudinal preparations exhibit minimal change. It was with such venous rings that Gunn & Chavasse (40) first demonstrated clearly that veins contract strongly in the presence of adrenergic drugs. This adrenergic response has remained somewhat

of a reference standard for comparing other agents, and for evaluating the effectiveness of other techniques for measuring venous tone. The action of many other agents has been examined in isolated preparations, so that there has developed an appreciable literature on the pharmacology of veins (28, 30, 61). Although the basic importance of these in vitro studies must be recognized, such techniques give us limited insight into the physiological responses of veins in vivo.

Direct Observation

The simplest method for detecting activity of the muscular elements of a vein in vivo is to observe changes in the caliber of the vein. Many such observations have been reported and much valid information has been deduced from such observations. As a general approach to the problem, however, this technique cannot be accepted as reliable. The observer can only detect changes in the volume of blood within the vessel. This change in blood volume may be caused by *a*) changes in flow through the peripheral vascular bed, *b*) alterations in the pressure and/or resistance to flow in more central portions of the venous channels, *c*) changes in the extravascular tissue pressure, or finally *d*) changes in the venomotor tone in the vessel under observation. Unless the first three factors can be confidently excluded, it is hazardous to infer that the last factor is the crucial variable.

It is rare that simple observation of veins will justify sound conclusions as to the cause of changes in venous caliber. An exception to this exists in some of the better controlled microscopic studies in which attention is directed toward unique vessels in the microscopic field. In this case the observer has the advantage of being able to assess directly the rate of capillary flow as well as the caliber and flow of vessels in parallel and series with the vessel under study. The contributions of such studies of the "microcirculation" are reviewed in Chapter 27. At this point we would only stress the principle that any observer of blood vessels must be thinking in rigorous hemodynamic terms if he is to make valid inferences from his observations, and refrain from any conclusions in regard to venous tone without reasonably secure evidence that other hemodynamic factors are not the significant ones.

Inferences from Venous Pressure

It has already been emphasized that inferences about venous tone based solely on venous pressure

are virtually worthless. Large portions of the venous bed are in a state of partial collapse, in which case pressures are not conditioned by vascular tone but by the interplay of extravascular pressures with intravascular dynamics. The small magnitude of venous pressure further complicates the problem, since an adequate definition of zero reference levels, appropriate to the specific conditions of the experiment, is often extremely difficult. Finally, in situations where venomotor activity exhibits any significant change, there are usually associated changes in cardiac activity and blood flow which produce passive changes in venous pressure. These further confound any valid assessment of venous tone.

Measurement of Pressure Gradients

Errors in attempting to draw inferences from isolated venous pressure might be reduced by measuring successive venous pressures along the venous gradient in conjunction with determinations of blood flow. Unfortunately, this approach is still confronted by the obstacle of collapse phenomena, aggravated in the case of intrathoracic and intra-abdominal veins by respiratory variations in extravascular pressure. The author is not alone among investigators who have spent frustrating hours attempting to interpret pressure gradients in such veins.

An older method for surmounting this obstacle in the larger veins was introduced by Donegan (19). He selected appropriate vein segments which could be isolated and perfused artificially, at sufficient rates to keep them well distended, and could yield meaningful pressure gradients. By judicious selection of the segment to be perfused, it is possible to preserve innervation to the vein and thus study the normal venomotor responses of such a vein segment *in vivo*. This technique has yielded a great deal of significant information in the hands of Fleisch (25), Gollwitzer-Meier (35, 36), and others. Unfortunately such preparations are rather difficult to prepare and maintain in good reactive condition, perhaps due to the trauma of isolation and double cannulation, possible interferences with vasa venarum circulation, temperature changes, and other artifacts introduced by the artificial perfusion. Fleisch particularly stresses the precautions which must be observed if a reactive preparation is to be obtained. This technique can therefore only be trusted when significant positive results are obtained; it is difficult to dissociate valid negative responses from deterioration of the preparation.

Another method of avoiding the collapse problem would be to proceed out far enough into the peripheral venous system to areas of steeper pressure gradients and higher absolute pressure levels, preferably in superficial areas where one can be confident that extravascular pressures will never approach the order of magnitude of intravascular pressures. A very significant advance is therefore represented by the work of Haddy (27, 41-45) who has employed fine plastic catheters and passed them in a retrograde direction into minute peripheral blood vessels, such as those of the paw. This retrograde catheterization must avoid areas with valves. By simultaneously recording pressures from minute vessels approached from both the arterial and the venous sides, and also from the corresponding large arteries and veins, he has been able to plot the pressure gradient through the total vascular bed. When combined with flow measurements, the flow resistance of each segment of the bed may be calculated. As has been previously discussed, moderate changes in the pattern of flow resistance and pressure gradient in local segments of the peripheral venous bed may not produce any alterations in the total capillary-to-heart pressure flow gradient; yet these changes will signify alterations in venous tone and the shifts in venous capacity which presumably result. With more intense venoconstrictor responses, venous resistance may become elevated to the point that capillary pressure rises, in which case this technique also becomes a very useful adjunct to the study of factors leading to tissue edema (41).

This technique has proven quite fruitful in the analysis of the effect of a variety of agents on the peripheral venous system. One example is shown in figure 9. The upper part of this figure indicates the pressures recorded from the vessels in the foreleg of a dog that was being perfused artificially at a constant rate; below are plotted the resistances calculated from the flow and pressure gradient data. On the left of the figure, the innervation was intact and vascular tone was high, as reflected in a high arterial pressure. Administration of 5-hydroxytryptamine (serotonin) produced a significant drop in pressure and resistance on the arterial side, particularly in the smaller vessels, attributed to antagonism of the adrenergic constrictor mechanism. In contrast, there was a dramatic rise in small vein pressure, interpreted as due to a direct constrictor action of this drug on the veins. Following denervation, the right of the figure indicates a low initial pressure on the arterial side because of a loss of sympathetic tone. Under these conditions, 5-hydroxytryptamine is observed to produce a significant

FIG. 9. Pressure gradients and resistance changes recorded from the foreleg and paw of a dog that was artificially perfused at a constant rate of flow, demonstrating the application of the Haddy technique (45).

constriction of the large arteries and veins, and only a minor change in the smaller vessel segment.

The fact that pressures in minute vessels show considerable pulsatile variation (41, 55), presumably associated with a type of venovasomotion (44), renders such measurements of greater qualitative than quantitative value, since it is difficult to have faith that the discrete vessel from which the peripheral pressure was recorded is accurately representative of the mean pressure in the peripheral venous bed as a whole. This reservation is reinforced by the possibility that the catheter might be wedged so that the recorded pressure represents that of a collateral somewhat remote from the catheter, and also the possibility that the presence of the catheter itself might alter pressure-flow dynamics. Nevertheless, if one keeps these reservations in mind, and takes precautions to be extremely critical of instrumental techniques and record analysis so as to exclude the many possible artifacts which may creep into a method of this type, this appears to be one of the most valuable techniques currently available for studying peripheral venous

function. It should be appreciated that this method also has the merits of being applicable to human studies (88).

Pressure Measurements in an Occluded Venous Segment

Doupe and associates (20) appear to have been the first to have employed the method of isolating a segment of a superficial vein between a pair of compressing wedges. If the wedges are placed so that the intervening segment is free of branches, this creates a blind cul-de-sac with an entrapped volume. If a needle is then carefully introduced into this segment, it is possible to record pressures in a system of fixed volume, hence any change in pressure must reflect a change in the muscle tone. In actual practice, it appears to be necessary to distend the vein with a considerable volume increment so as to yield basal pressures of the order of 40 to 60 cm H₂O in order to achieve significant pressure changes. This also serves the purpose of elevating the recorded pressure out of the range of confusion with extravascular pressure effects.

A recording from such a preparation is illustrated in figure 10. This illustrates one feature that is conspicuously demonstrated by this technique: the marked influence of psychic stimulation on venomotor response as the experimental subject witnesses the preparation of some experimental maneuver which he is to undergo. Since responses of the type illustrated in figure 10 disappear after sympatholytic drugs, there can be little doubt as to their venomotor origin. This technique has been exploited with considerable success (14, 68) and is the most direct qualitative method for studying the venous reactions of the human subject. Because it concerns itself with a unique venous segment, however, it does not appear feasible to standardize the quantitation of pressure responses observed in such studies.

A variation of this technique is to introduce a small cylindrical balloon into a vein segment and measure pressure changes in this balloon. This obviates the necessity of selecting a segment free of branches, and gives greater confidence that the observations are being obtained from a closed system. As with the method previously described, it also seems essential to distend the balloon to pressure of 30 cm H₂O or higher in order to observe significant changes. Salzman (81) has successfully applied this technique to the study of the venomotor response to pressoreceptor reflexes. Connolly & Wood (18), on the other hand,

FIG. 10. Pressure changes recorded from a segment of a superficial vein of the forearm that had been isolated between wedges and kept at constant volume. [From Duggan *et al.* (21).]

were unable to record temperature reactions in superficial veins in man by this technique, even though veins adjacent to that containing the balloon exhibited obvious caliber changes. The author has similarly been unsuccessful in attempting to get sufficient response for accurate analysis in a variety of applications of this technique to various dog preparations. Further studies are in order to determine the full potentialities and limitations of this method.

Another type of method which is based on the same principle was introduced by Hooker (54) and has been adapted to human studies by Wallace (87, 88). By use of a pressure cuff on the arm, pressure is first developed to occlude venous drainage and produce venous congestion, and then further elevated to stop all blood flow to the arm. Venous pressures measured between 2 and 8 min after obstruction to blood flow show a slow decline, presumably due to capillary transudation. Venomotor stimulation produces pressure changes superimposed on this slow decline. Although this method has yielded clear qualitative evidence of venomotor reactions (64), and possibly has some merits of simplicity, it introduces a number of complicating features, such as prolonged ischemia, which would vitiate precise quantitation and therefore place it in an unfavorable position as compared with other methods that are available.

Pulse Methods

Pulsatile changes in the volume contained within a vascular segment will produce pulsatile pressure changes, the magnitude and rate of transmission of

which are determined by the elastic properties of the vessel wall. Since muscle tone is one of the factors influencing elasticity of the venous wall, this suggests another possible approach to an assessment of venomotor tone. Unfortunately, the pulsations which occur normally in the venous system are too small in magnitude and too complex in etiology to be susceptible to this type of analysis.

Peterson (72, 73) has overcome this limitation by generating pulses artificially with a high speed injection system. There results a momentary peak of pressure which increases in magnitude as venous tone increases. As yet, limited applications of this type of method have been reported. The author has had extensive experience with a related phenomenon that he has referred to as the "acceleration transient" which appears at the moment of initiating a constant speed injection into a vein. It is clear that many details at the tip of the injection cannula can influence the pressure peak produced. The exact dimensions and orientation of the injection orifice in relation to the vessel lumen are of critical importance in determining the exact pattern of pressure development, and this problem can be gravely augmented by the tendency for some veins to develop a segment of local constriction in the area of cannulation. Extending the orifice to a site somewhat remote from the point of cannulation introduces problems of proper orientation of the injection tip, and also requires pressure recording through a separate channel in order to prevent the flow resistance of an elongated injection cannula from dominating the pressure recording. Although the potentialities of such a pulse method

should not be overlooked, at present it has not been developed to the point that it can be applied to the accurate measurement of venous tone.

Venous Distensibility Patterns

As has been pointed out in reference to figure 5, constriction of a vein alters its distensibility diagram. The maximally dilated vein exhibits a smooth curve convex toward the volume axis. As progressively more constriction occurs, the distensibility curve is transformed into a sigmoid form showing initially a relatively rapid rise in pressure with initial volume increments, a very much slower pressure rise as intermediate volumes are added, and then a final steep rise in pressure as still further volume is introduced. If the rate of venous distension is carefully controlled so as to prevent stress relaxation effects from distorting the slopes of these curves, evidence of venoconstriction should be obtainable from studies of the shape of the distensibility curve.

The first application of this principle was presented by Capps (16) using a plethysmographic method on the human forearm. The use of the plethysmographic technique for venous distensibility measurements was a logical outgrowth of measurements of blood flow by the Hewlett & Van Zwaluwenburg method (50). In the latter method, while the distal portion of the arm is enclosed in a plethysmograph to record arm volume, a pressure cuff around a proximal portion is suddenly inflated to a pressure slightly less than the arterial diastolic pressure. This suddenly blocks venous outflow from the arm without any immediate interference with arterial inflow, and hence the arm will increase in volume at a rate equal to the rate of blood flow into the arm. After a short interval, this blood flow will be reduced by the progressive congestion of the distal vascular bed. The point is reached eventually where arm volume becomes relatively stable, and this must mean that venous pressure has increased to equal cuff pressure so that venous blood will be forced past the occluding cuff at a rate equal to the reduced inflow rate. As has been pointed out earlier, the most significant factor in the change in the volume of the arm under these conditions is the congestion of the venous bed (17, 39). Therefore, using stepwise increments in pressure in the occluding cuff yields a series of increments in arm volume which, as a reasonably good first approximation, represents the increase in venous volume at the corresponding occluding pressures. With this method, Capps obtained clear evidence of

a sigmoid distensibility curve in veins constricted by cold and other venoconstrictor stimuli, while dilated veins exhibited a typical convex distensibility pattern.

Many subsequent authors have reported on venomotor reactions using the plethysmographic method. A number of modifications in technique have been introduced to minimize the artifact associated with inflation of the pressure cuff, and to permit accurate pressure reference levels. Errors in the pressure-volume determinations due to unequal distribution of pressure in the transitional zone at the margin of the plethysmograph may be corrected by use of a double plethysmograph. Both compartments are exposed to equal pressures, but only the distal segment is used for volume recording (93). Burch (12) has used another method to correct for the occlusion artifact in developing the plethysmographic technique for use on the digit. By measuring the volume change produced by the venous occlusion cuff during an interval when all blood flow had been arrested by arterial compression, he obtains an uncomplicated record of the artifact alone, which can be subtracted from the blood flow curves. When these corrected curves are compared with unoccluded digital pulse curves, he feels that he can analyze arterial inflow and venous outflow dynamics with sufficient accuracy to quantitate the phasic changes that occur during each pulse wave.

Other plethysmographic devices, such as the mercury-in-rubber resistance strain gauge (89) or the impedance plethysmograph (75), may be adapted for venous studies, although the simplicity of their application should not encourage neglect of establishing their quantitative reliability.

There is one inherent difficulty in the plethysmographic method for distensibility determinations, however, which in the opinion of the author has not been adequately resolved. The sudden increment in venous outflow pressure will have its most direct effect in elevating venous pressure; to a lesser extent it will elevate capillary pressure, and to a slight extent it will elevate the distal portions of the arterial pressure gradient. This justifies the assumption that most of the immediate volume change will occur on the venous side, an assumption which has been reasonably well substantiated. On the other hand, the elevated capillary pressure promotes capillary transudation, so that the recorded volume never reaches a true plateau, but shows a slow increase persisting after the initial major increase. Owing to the time-dependent characteristics of vascular elasticity, moreover, venous distension occurs rapidly at first and

then distends more slowly toward its equilibrium condition. As a consequence, volume increase due to the delayed distension of the veins merges indistinguishably with the volume increase due to capillary leakage. One might attempt to control this problem by using rigorously standardized intervals of pressure exposure before reading the volume. Since the magnitude of the effect increases as higher pressures are reached, however (cf fig. 6), virtually all reports of the use of the plethysmographic technique have described vague and highly subjective criteria for selecting the end point at which to read the volume. There results a random scatter of the determined points which often obscures the actual form of the distensibility curve. Therefore most recent authors have abandoned any attempt to interpret the form of the curve, and base their interpretations solely on the total volume increment between two arbitrary pressure levels. We will return to consider the significance of this type of interpretation after first considering other techniques which have focused on the form of the distensibility curve.

The author has developed a method based upon the change in distensibility pattern of intestinal veins in the dog. After surgical isolation of the blood flow through an intestinal loop, the circulation is momentarily interrupted while blood is injected in a retrograde direction into the venous bed. By dividing the volume change required to raise the venous pressure from 10 to 20 cm saline into the volume change required to raise the pressure from 20 to 30 cm saline, it is possible to calculate a "venomotor index" which expresses numerically the degree of sigmoid curvature. This method has been standardized by use of a motor-driven syringe and accurate timing of the injections so that highly reproducible readings can be obtained, permitting following changes in venomotor tone in an animal over a period of several hours (5). Also, if injection rates are adjusted so as to yield equivalent rates of pressure rise in preparations of different sizes, reasonably quantitative comparisons can be made between different animals.

Unfortunately, this method is not without its limitations. There remain some unanswered questions as to the exact nature of such a retrograde injection. The method was originally designed on the assumption that there were no valves in this bed. Since India ink injections invaded the minute vessels of the viscus, and yet there was no suggestion of any rise in pressure on the arterial side of the loop, there was an empirical basis for accepting with some confidence that the distensibility measurements were representative

of the venous bed. Recognition that these veins are in fact well supplied with valves of rather poor competence (fig. 1) raises the question as to whether the valves might be making some contribution to the pattern of the distensibility curves. To admit this possibility, however, would not alter the actual interpretation of the data. The retrograde pressure required to force blood past a valve must be a function of the muscular tone in the wall of the vessel. A dilated vein should develop valvular incompetence quite readily, while a constricted vein should be able to withstand somewhat higher back pressures before developing incompetence. Such valve action might act to exaggerate the degree of sigmoid curvature in the distensibility of a constricted venous bed, but this would reinforce rather than detract from the acceptance of the degree of sigmoid pattern as an index to the degree of venoconstriction.

A more serious difficulty relates to the moderately extensive surgical preparation required in the technique for setting up the loop, which taxes the compensatory ability of the animal. Any further major manipulation, such as an open-chest procedure, often leads to deterioration of its circulatory status. This method is also restricted to the analysis of pressure-volume increments; a satisfactory quantitation of the total venous volume has not yet proved feasible. This negates some of the potential value of obtaining a quantitative index, since it cannot be related in meaningful terms to total circulatory function. Although this is a defect which this technique shares in common with most other methods for assessing the functional activity of the peripheral venous bed, it is important not to lose sight of the ultimate goal of being able to evaluate quantitatively the contribution of the peripheral venous bed to over-all circulatory dynamics.

A further extension of this general method has recently been introduced by Bartelstone (7), who has studied the pattern of pressure development behind a sudden obstruction of the vena cava. His results also afford evidence of the sigmoid distensibility pattern which develops with venous constriction, although in this method the quantitative interpretation is complicated by simultaneous changes in flow.

Distensibility by Volume Increment

As implied above, the plethysmographically recorded distensibility of the venous bed has been subjected to two types of interpretation. Capps stressed the pattern of the data, with the constricted veins showing relatively less distensibility at low pressures

and greater distensibility at intermediate pressures. A majority of authors, however, have stressed the increment in volume between two arbitrary pressures, and interpreted a decrease in the volume change between these two pressures as an indication of venous constriction.

To argue that a decreased volume increment is an indication of venoconstriction might appear to represent a conflict with our previous discussion of distensibility patterns. The great distensibility of the constricted vein over the intermediate range of the sigmoid curve would seem to demand a great total distensibility in the constricted vein. As can be appreciated by reference back to figure 5, however, a comparison of the volume increments in constricted and dilated veins between any two arbitrary pressures will yield different relationships at different pressure levels. In the experiment shown in figure 7, for example, the injection happens to have been stopped at the point that the pressure-volume relationships in the constricted and dilated veins were virtually identical; a comparison of the total pressure-volume increment would offer no suggestion of the significant differences in distensibility above and below this particular point.

The author is not aware of any data, obtained with sufficient precision to identify the pattern of the distensibility curve, in which apparent discrepancies in the interpretation of decreased venous distensibilities cannot be resolved by reference to the pressure level. To illustrate this point, the data in figure 11 were taken from a report of a reasonably well-standardized application of the plethysmographic method and described by the authors as a "typical" response.

FIG. 11. Volume increments in the human forearm recorded by congesting the veins to successively higher pressure. Open circles indicate control values; solid circles are the volumes determined while infusing noradrenaline at the rate of 0.4 $\mu\text{g}/\text{min}$. [Redrawn from Glover *et al.* (34).]

The authors interpreted these data as demonstrating that noradrenaline acts to decrease venous distensibility. One cannot argue with such an interpretation as a correct description of the data as far as they go. Nonetheless, this interpretation ignores the different form of the curves. Although the control data exhibit a relationship convex to the volume axis, the data recorded during noradrenaline infusion are clearly concave to the volume axis. These data are therefore completely compatible with the pattern interpretation used by Capps and generalized in figure 5. An extrapolation of the curves in figure 11 to higher pressures would clearly lead to a relative increase in the total distensibility of the constricted vessels and a relative decrease in the total distensibility of the dilated vessels. Unfortunately, since the plethysmographic method cannot be used effectively when venous congesting pressures approach arterial pressures, this technique does not appear suitable for bringing out the full sigmoid distensibility pattern in these veins. It should be recognized that veins in the extremities are subjected to much greater hydrostatic loads than are visceral veins, and therefore it would not be at all surprising to discover that much higher pressures were required to achieve the full sigmoid pattern in arm veins.

It is of interest to note that a similar argument has arisen in reference to isolated vein preparations. Leonard & Sarnoff (59) state unequivocally that a constrictor drug always reduces venous distensibility. Inspection of the Leonard and Sarnoff report, however, reveals a definite alteration of the pattern of their distensibility data which is quite compatible with the suggestion that sufficient stretch will eventually reveal a very significant distensibility of the constricted vein.

Nevertheless, there is another factor in these distensibility characteristics which must be considered. The original interpretation of the sigmoid curve visualized that at high pressures the constricted vessel was pulled out to the same dimension as the dilated vessel, and thus demands that the total distensibility must be greater in the constricted vessel. As has been discussed earlier, the validity of this interpretation is open to some question. It is conceivable that a sigmoid distensibility pattern may be compatible with some reduction in total distensibility. If, in addition, dilated veins were in a state of partial collapse at the point that the initial volume was measured, this would augment the possibility of observing a greater total distensibility in the dilated vein.

One is therefore justified to interpret distensibility data in whatever fashion appears compatible with the responses observed with his particular method. Since there is overwhelming evidence that adrenergic drugs are potent venoconstrictors, a reproducible response to such drugs may be used as a reference standard to which responses evoked by other stimuli may be related. It would nonetheless be desirable to adopt accurately standardized methods for distending veins so that data will have greater validity. In view of the significant stress relaxation and creep phenomena demonstrated by veins, one can scarcely hope to obtain any precise information by making measurements "as soon as the volume seems reasonably stable."

SUMMARY OF VENOMOTOR RESPONSES

From the great variety of techniques that have been employed for the assessment of venomotor activity, a wealth of information has been obtained which demonstrates at least qualitatively the types of stimuli which evoke venomotor responses. In table 1 are listed responses which stand without controversy as representative of the active responses of the venous system. It should be understood that this listing does not pretend to be comprehensive or cover any significant fraction of the full literature on the subject; in general it has proven convenient to confine the citations in this table to reports which have been referred to for other purposes in our previous discussion. This evidence of a broad spectrum of reactivity suggests that the venous system must play an important function in active regulation of the circulation as a whole. For a discussion of this important aspect of venomotor action, the reader is referred to Chapter 32. The remainder of our comments will be confined to response characteristics which appear to be of some unique importance to the venous system.

Most investigators of the venous system have been impressed with the fact, first emphasized by Gollwitzer-Meier (36), that the venous system appears to act synergistically with the arterial system. This is emphasized in the evidence presented in table 1; with the exception of histamine, all responses listed are direct counterparts of similar reactions known to occur on the arterial side of the circulation. Beyond this qualitative similarity, the interesting question arises as to the relative sensitivity of arteriomotor

TABLE 1

| <i>Venoconstrictor Responses</i> | <i>References</i> |
|----------------------------------|----------------------------------------------------------|
| Adrenergic drugs | 2, 4, 14, 19, 25, 34, 40, 43, 59, 61, 63, 82, 88, 91, 93 |

and venomotor systems. The literature contains definite suggestions that the venous system may have a greater sensitivity (55, 92) and also make a greater contribution to the total circulatory response (53), although more information is needed to permit sound generalizations.

There are a few instances, however, in which the responses of the venous system appear to be unique. One is the influence of 5-hydroxytryptamine previously discussed in reference to figure 9. Haddy's data would indicate that this compound is more effective in producing venoconstriction than it is in blocking pre-existing venous constriction resulting from high sympathetic tone, while for the small vessels on the arterial side of the circulation, the sympathetic blockade can dominate the direct constrictor action of the compound. Therefore, 5-hydroxytryptamine shares with histamine the capacity to produce both venoconstriction and arteriolar dilation; as a consequence both of these compounds have the capacity to induce edema formation. There is an indication that local tissue acidity may also have such an action (27, 32). An inverse type of dissociation between arterial and venous effects has been reported to occur in circulatory shock, where venoconstrictor mechanisms fail at a point at which arterial constrictor tone is still well maintained (5).

A particularly interesting dissociation also appears to exist in reference to temperature effects. While cold produces significant constriction of cutaneous arterioles, it is even more effective as a venoconstrictor

tor. This cold venoconstriction has a significant reflex basis as well as a local component (18). As a consequence, capillary pressure should rise, accounting for the increased transudation of fluid and the tendency for the hematocrit to rise in cold. Secondly, the fall in temperature so interferes with dissociation of oxyhemoglobin as to produce some tissue anoxia. The anoxic metabolites tend to act as vasodilators competing with the cold constriction of the arterioles, but seem to have no capacity to cause venodilation. As a consequence, the skin becomes plethoric because of some arterial inflow in the face of a continued resistance to venous outflow. Rewarming of the tissue will now cause arteriolar dilation. There is considerable evidence, however, that the veins do not dilate in response to heat (39, 42, 56, 93). Indeed, the extreme venoconstriction produced by the previous cold stimulus seems to dissipate slowly after the tissue is rewarmed, so that during the initial phase there is significant arteriolar dilation in spite of persisting venous constriction (42). This accounts for the extreme degree of plethora and tendency toward edema formation which is observed in the rewarming phase.

Finally, attention should be called to fragmentary information relating to the possibility of venovenous reflexes. Apart from the general homeostatic regulators of the circulation, such as the arterial pressoreceptor mechanism and the chemoreceptor responses, are there mechanisms for adjusting venous capacity as a function of the venous pressure? In view of the importance of the central venous pressure in determining cardiac output, circulatory homeostasis would be enhanced if there were such a mechanism for adjusting venous capacity to central venous pressure, so that the venous reservoir tended to expand in response to an increase in venous pressure and contract in response to a decrease in venous pressure.

There are several suggestions that such a mechanism exists. With acute hypotension produced by vagal bradycardia, Fleisch (26) observed an initial venous constriction, attributable to the carotid sinus reflex, followed by a secondary venous dilation which he felt was associated with the venous congestion produced by the bradycardia. A very similar observation was reported by Schretzenmayr (82) in the response to adrenergic drugs. Although these drugs usually produced a conspicuous venoconstriction, in instances where the circulatory load became so great as to momentarily embarrass the heart and produce cardiac distension, there appeared

to be some mechanism that was counteracting the venous constriction. More direct evidence of this mechanism has been provided by the author (6), who demonstrated venodilation to be produced reflexly when venous congestion was produced by inflating a balloon in the thoracic vena cava. It is important to note, however, that to demonstrate this effect it proved quite essential to prevent changes in pressure on the arterial side of the circulation. Unless such precautions are taken, the arterial pressoreceptor system dominates the circulatory responses, and the venovenous reflex mechanism described above is completely overwhelmed.

This dominance of the arterial pressoreceptor reflexes accounts for a number of observations which otherwise would argue against the venovenous reflex. Wood (93) has demonstrated reflex venous constriction in man associated with venous congestion produced by occluding cuffs on the extremities. Inasmuch as they observed a reflex tachycardia as well as arterial constriction associated with what was estimated to be a 15 per cent reduction in circulating blood volume, this response would relate primarily to arterial pressoreceptor mechanisms. In confirmation of this, when the subjects were in a supine position so as to minimize pooling of blood with venous tourniquets, neither the venous reflex nor other signs of compensation to arterial hypotension were observed. Similarly, Page and co-workers (68) found venoconstriction to be produced by the Valsalva maneuver, which would also be explainable in terms of baroreceptors on the arterial side dominating the simultaneous effects of congestion on the venous side.

There remains the problem of interpreting the evidence presented by Burch (13) that patients in congestive heart failure are characterized by an augmented venomotor tone. If one assumes that the only significant feature in this condition is venous distention, this finding would not be compatible with the postulation of a reflex venodilation in response to venous distension. It may be of significance that Burch found definite evidence of venoconstriction only in those patients who were rather severely decompensated and in whom numerous other sources of reflex stimulation might therefore have been operable. Our inability to define more clearly the exact nature of the venomotor reactions occurring in such an important clinical problem should afford adequate stimulus to seek still further clarification of the nature of venomotor control.

Summary

INTRODUCTION

THE TERM "VENOUS RETURN" means very simply the flow of blood from the veins into the heart, and this, obviously, can be divided into "systemic venous return" and "pulmonary venous return." The function of the veins and the importance of venous return have been covered from different points of view in several important monographs (31, 70) and reviews (72, 82–85, 133, 137). Also, the basic characteristics of the veins as blood vessels are reviewed by Alexander in Chapter 31. Therefore, the purpose of this chapter will be to discuss especially the regulation of venous return and secondarily the associated factor venous pressure.

Though the venous return is normally exactly equal to ventricular output, this may not be true for short periods of time. However, when the venous return is greater than the ventricular output, blood will accumulate in the heart. During the ensuing few heartbeats a new state of equilibrium will develop, and venous return will again become equal to the output. Yet, since there are times when venous return and cardiac output are not equal, it is justified to use the term "venous return" separately from the term "cardiac output."

Normally, in speaking of cardiac output, one thinks principally of cardiac activity, whereas in speaking of venous return, he thinks of all the functions of the peripheral circulation that have to do with blood flow into the heart. For this reason many circulatory physiologists consider cardiac output to be regulated principally by the heart and venous return to be regulated principally by peripheral factors. By all means, the reader must be cautioned at the outset against this viewpoint, because except for instantaneous periods of time, any factor that affects cardiac output also affects venous return, and any factor that affects venous return also affects cardiac output. This principle can be expressed in another way: The circulatory system is a circuit, and the total flow of blood through any one cross section of the circuit is exactly the same as the total flow through any other cross section.

Principles of Circuit Analysis as They Apply To Venous Return

Often, physiologists have attempted to analyze the regulation of venous return entirely on the basis of local factors in the veins and right heart. However, this is a completely fallacious approach, for any factor that affects blood flow in any single unit of the entire circulation will likely at the same time affect venous return. For this reason, a complete circuit analysis of the entire circulation is required for any degree of accuracy in determining the factors that regulate venous return (46, 47, 78, 81, 126-128, 192). This means that the same factors that regulate cardiac output are those which also regulate venous return. In general, these can be divided into two major groups: those concerned with the ability of each side of the heart to pump blood, and, second, those concerned with the ability of blood to flow through the two divisions of the peripheral circulation, the systemic circulation, and the pulmonary circulation. In this chapter we will be concerned with both of these groups of factors and with the manner in which they

operate together to regulate blood flow in the circulation. However, the contribution of the heart to the regulation of blood flow in the circulation is discussed in great detail in several other chapters, including especially those by Hamilton, Sarnoff & Mitchell, Brecher, and Rushmer (Chapters 17, 15, 23, and 16, respectively). Therefore, in this chapter we will discuss the cardiac factors only briefly while discussing the peripheral factors in far greater detail.

THE PROBLEM. Figure 1 depicts a highly simplified diagram of many of the important factors that must be considered in analyzing blood flow around the circulatory circuit. First of all, we note in the diagram the term blood flow (F) appearing at four different points: 1) at the output of the right heart, 2) at the output of the pulmonary circulation, 3) at the output of the left heart, and 4) at the output of the systemic circulation. Under steady-state conditions, the blood flow at all of these four points will be exactly equal. Yet, in a circulatory analysis we must consider them separately, because they are not always equal, and during the periods of time when they are unequal, blood will be actively translocated from one part of the circulation to another, thus causing new equilibrium conditions to develop. Now to describe the

FIG. 1. Circulatory schema, showing the effects of individual factors in different parts of the circulation on other functions of the circulation. Each arrow represents a separate effect, and a composite analysis of the circulation requires that all these effects be considered simultaneously as explained in the text.

events depicted in figure 1, we can start by pointing out that each arrow represents an effect of one factor on another factor. The different effects denoted in this figure can be listed as follows:

- (1) Right heart blood flow (F_{rh}) directly affects pulmonary arterial pressure (P_{ap}).
- (2) Right heart blood flow (F_{rh}) inversely affects systemic venous pressure (P_{vs}).
- (3) Pulmonary arterial pressure (P_{ap}) inversely affects right heart blood flow (F_{rh}).
- (4) Pulmonary arterial pressure (P_{ap}) directly affects pulmonary blood volume (V_p).
- (5) Pulmonary arterial pressure (P_{ap}) directly affects pulmonary blood flow (F_p).
- (6) Pulmonary blood volume (V_p) inversely affects pulmonary resistance (R_p).
- (7) Pulmonary resistance (R_p) directly affects pulmonary arterial pressure (P_{ap}).
- (8) Pulmonary resistance (R_p) inversely affects pulmonary blood flow (F_p).
- (9) Pulmonary blood flow (F_p) directly affects pulmonary venous pressure (P_{vp}).
- (10) Pulmonary venous pressure (P_{vp}) directly affects pulmonary blood volume (V_p).
- (11) Pulmonary venous pressure (P_{vp}) inversely affects pulmonary blood flow (F_p).
- (12) Pulmonary venous pressure (P_{vp}) directly affects left heart flow (F_{lh}).
- (13) Left heart blood flow (F_{lh}) inversely affects pulmonary venous pressure (P_{vp}).
- (14) Left heart blood flow (F_{lh}) directly affects systemic arterial pressure (P_{as}).
- (15) Systemic arterial pressure (P_{as}) inversely affects left heart blood flow (F_{lh}).
- (16) Systemic arterial pressure (P_{as}) directly affects systemic blood volume (V_s).
- (17) Systemic arterial pressure (P_{as}) directly affects systemic blood flow (F_s).
- (18) Systemic blood volume (V_s) inversely affects systemic resistance (R_s).
- (19) Systemic resistance (R_s) directly affects systemic arterial pressure (P_{as}).
- (20) Systemic resistance (R_s) inversely affects systemic blood flow (F_s).
- (21) Systemic blood flow (F_s) directly affects systemic venous pressure (P_{vs}).
- (22) Systemic venous pressure (P_{vs}) inversely affects systemic blood flow (F_s).
- (23) Systemic venous pressure (P_{vs}) directly affects systemic blood volume (V_s).
- (24) Systemic venous pressure (P_{vs}) directly affects right heart flow (F_{rh}).

Now we have completed the circuit, giving most of the major factors within the circulation that affect each other; obviously, a change in any one of these will change all the others. However, this has been a highly simplified schema, for, onto these basic mechanical factors, we must superimpose the effects of

circulatory reflexes, hormones, special conditions such as exercise, hemorrhage, myocardial infarction, or any other condition that can affect the function of any single segment of the circulation.

To complicate the picture further, we must also note how greatly simplified some of the individual effects illustrated in figure 1 have been made. For instance, one of the effects noted in this figure is the direct effect of systemic venous pressure on right heart blood flow. Actually, the systemic venous pressure does not directly affect the right heart blood flow but instead affects the filling of the right heart. This in turn affects the degree of stretch of the cardiac musculature, which then affects the force of contraction. Finally, it is this force of contraction that directly affects the right heart blood flow. Thus, it can be seen that four steps have actually been compressed into one in the simplified diagram of figure 1.

We can summarize the problem, therefore, by pointing out that the regulatory factors of the circulatory system can be divided into literally hundreds or even thousands of individual factors distributed throughout the circulation. Indeed, even closure of a single capillary exerts its infinitesimal effect on the functions of all other parts of the circulation. This, then, is the problem with which we are faced in this chapter, to unravel the myriad of different factors that affect blood flow in the circulation and to determine those that are especially important in relation to venous return.

SOLUTION TO THE PROBLEM. Several reasonably satisfactory solutions to the above problem have now been offered, and all of them have taken the same general form [Guyton (81), Grodins (78), Warner (192)]. First, in each of the solutions, many or most of the parallel segments of the circulation are grouped together. For instance, in a general solution of the problem one would not attempt to analyze the effect of occluding each single arteriole on the circulatory dynamics, but, instead, all of the arterioles are grouped together. Similarly, the capillaries are grouped together, the venules, the large arteries, the large veins, and so forth. This is done separately for the systemic circulation and pulmonary circulation. The next step in the solution is to group the individual segments of the circulation into several convenient larger segments and then to analyze the function of each of these larger segments separately, this followed by a synthesis of the separate analyses into a composite analysis. Thus, as we shall show later in the chapter, the function of the right heart can be analyzed sepa-

rately; then the function of the pulmonary circulation can be analyzed; then that of the left heart, and that of the systemic circulation. Once these four analyses have been made they can be put together either algebraically or graphically to derive a composite analysis of the entire circulation. In a still further simplified analysis one can even analyze the function of the entire heart and pulmonary circulation as a single segment of the circulation, such as is usually done in studying the heart-lung preparation. Then the systemic circulation can be analyzed as a separate segment and the two analyses put together to provide a composite analysis for the entire circulation.

Obviously, the more extensively the different parts of the circulation are grouped into large circulatory segments the less accurate becomes the over-all analysis. Furthermore, the type of analysis and the type of grouping of circulatory segments that will be used will depend to some extent on the factors of the circulation and the type of circulatory stress one wishes to study. Fortunately, it is usually possible to find some specific grouping of circulatory segments that is both simple and yet accurate enough for the desired purpose.

The Classical Analysis of Venous Return— Vis a Tergo and Vis a Fronte

The classical method for analyzing the factors that affect venous return has been to consider that two forces affect blood flow from the systemic veins into the right atrium (31, 70, 132, 133): 1) the force from behind, called "vis a tergo," which pushes blood along the veins toward the right atrium, and 2) the force from in front, that is, from the right heart itself, called "vis a fronte," which either impedes blood flow into the heart or perhaps at times aids the flow. Actually, the vis a tergo is the force that remains after dissipation of the arterial pressure during the course of blood flow through the systemic vessels. Conversely, the vis a fronte is a back pressure from the heart that depends principally on the over-all pumping activity of the heart. If the heart is very active as a pump, the back pressure will be low and consequently the vis a tergo can force blood into the heart with ease. Conversely, if the pumping activity of the heart is weakened, then the back pressure from the heart will be greatly enhanced, this in turn impeding the flow of blood into the heart.

A specific factor that must be considered in relation to the vis a fronte is the possibility of suction of blood into the heart caused by relaxation of the cardiac

chambers or caused by respiratory movements, and a vast segment of the literature on venous return has concerned itself with these considerations. They will be discussed in detail in the latter part of the chapter.

History of More Complete Circulatory Analyses

Unfortunately, the classical analysis of venous return has never been quantitative because such a simple presentation does not provide an adequate basis for delineating either the many different peripheral or cardiac factors that affect vis a tergo or those that affect vis a fronte. For this reason, progressive attempts have been made—very slowly, to be sure, but beginning about one hundred years ago—to provide more complete analyses of the circulation, with consequently higher degrees of quantitation of the interrelationships between the individual circulatory factors. The first real attempt in this direction seems to have been made by Weber (194) in 1850, at which time he expressed in general the complexity of the relationships illustrated in figure 1, though not expressing these in precisely the same manner as shown here. From the literature it is equally as evident that these general principles have been well understood by Starling (179), Bolton (23), Starr (180, 182), Katz *et al.* (126–128), Daly *et al.* (46, 47), Rose *et al.* (168), and Rashkind *et al.* (158). Yet, it has been only in the last half decade that serious attempts have been made to provide composite analyses of the circulation. From our laboratory has come a graphical approach to this problem (81), both in a simplified version and in a more complex version, portions of each of which will be presented in this chapter. In addition to this, two different and closely similar algebraic analyses have been presented by Grodins (78) and by Warner (192). All these analyses are based on the general principles illustrated in figure 1. However, each of the analyses groups the components of the circulation somewhat differently, they go to greater or lesser degree into the details of either cardiac or peripheral circulatory factors, and they make slightly different basic assumptions. Yet, the results of these three entirely independent and different analyses are almost exactly identical. For this reason they all deserve the highest degree of consideration. Since each of these analyses is relatively complex and long, it would be impossible to present them all in this chapter. Therefore, this chapter will be limited to a presentation of the graphical analysis, and the serious student of this subject will be referred to the very complete and interesting algebraic analysis by

Grodins (78) and also to Chapter 50 by Warner in this *Handbook*, as well as to the paper presenting his algebraic analysis (192). The algebraic method of circuit analysis depends upon expressing the functions of the individual segments of the circulation in terms of mathematical equations. Then, for a composite analysis of the entire circulation, the equations are solved by standard methods for simultaneous equations.

SIMPLIFIED GRAPHICAL ANALYSIS OF VENOUS RETURN, CARDIAC OUTPUT, AND RIGHT ATRIAL PRESSURE

A simplified method for graphical analysis of venous return, cardiac output, and right atrial pressure depends upon dividing the circulatory system into two major segments. The first segment is a composite of the right heart, the lungs, and the left heart. The second segment is the systemic circulation. By studying flows and pressures at different points while stressing the circulation in any one of many different ways, one can analyze the circulatory functions of the heart-lung segment in *a*) the heart-lung preparation, or *b*) the intact animal. On the other hand, the functional characteristics of the systemic circulation can be studied *a*) in an isolated systemic system in which the entire heart or part of the heart is replaced by a pump (98), or *b*) in the intact circulation by measuring pressures and flows at different points while stressing the circulation. These studies yield graphical function curves that are complements to each other. These complementary curves can then be plotted on the same coordinates and thus solved by their points of intersection. The function curves depicting function of the heart-lung segment are called "cardiac output curves," and they are one form of Starling's curves of the heart. The curves depicting function in the systemic circulation are called "venous return curves." Before we can proceed further with this analysis we must now characterize the various types of cardiac output and venous return curves that occur in different circulatory conditions.

Cardiac Output Curves

In figure 2, the middle curve represents the normal cardiac output curve of the heart of a 10-kg dog. The shape of this curve has been confirmed by numerous investigators, beginning with Patterson & Starling (154) in 1914 and extending through studies by Katz (123), Krayer (131), and especially Sarnoff and his

FIG. 2. Cardiac output curves for the normal heart, for hyper- and hypoeffective hearts, and for hearts subjected to increased or decreased resistive loads.

colleagues (18-20, 38, 120, 171, 172). The quantitative values used in this graph were derived principally from the original quantitation made by Patterson and Starling, data presented by Sarnoff and his colleagues, and many measurements made in our own laboratories.

A particular problem in determining the quantitative values for the cardiac output curves has been the fact that almost all such curves have been recorded in open-chest animals. Yet, in circuit analysis we need to know the quantitative values for the cardiac output curves in the normal closed-chest animal rather than in the open-chest animal. We shall see below that the quantitative values for the curves change markedly upon opening the chest. The figures expressed in this chapter will be for the closed-chest animal unless otherwise specified, and the quantitative values that are presented are based upon curves obtained in open-chest animals but extrapolated to the closed-chest animal on the basis of unpublished determinations that we have made in this laboratory while stressing the circulation with rapidly increasing or decreasing blood volume.

Basically, three different groups of factors determine

the shape and quantitative values of the cardiac output curve. These are 1) the effectiveness of the heart as a pump, 2) the pressure against which the heart must pump, and 3) factors that affect the pressure on the outside of the heart.

EFFECTIVENESS OF THE HEART AS A PUMP. When the effectiveness of the heart as a pump increases, the cardiac output curve correspondingly increases, as illustrated by the upper curve of figure 2. That is, for any given right atrial pressure the cardiac output is considerably greater from the "hypereffective" heart than from the normal heart. There are only three major causes of a hypereffective heart; these are: 1) stimulation of the heart by the sympathetic nervous system, 2) inhibition of the parasympathetic nerves to the heart, and 3) hypertrophy of the heart. In each one of these instances the heart contracts with increased force or increased rate and consequently pumps more blood for any given input pressure than does the normal heart.

Figure 2 also illustrates the effect of a hypoeffective heart on the cardiac output curve. That is, for any given input right atrial pressure, the hypoeffective heart pumps far less blood than does the normal heart. Among the different factors that can cause a hypoeffective heart are *a)* myocardial infarction, *b)* coronary sclerosis, *c)* myocarditis, *d)* valvular heart disease, *e)* congenital heart disease, *f)* cardiac arrhythmias, *g)* hypothermia, *h)* abnormal electrolytes in the extracellular fluids, *i)* parasympathetic stimulation, *j)* sympathetic inhibition, or any other factor that reduces the ability of the heart to pump blood.

Obviously, there can be all degrees of hypereffectiveness or hypoeffectiveness of the heart. Therefore, an infinite number of curves would be required to depict the various degrees of pumping effectiveness of the heart under all different conditions. Yet, at any given instant in the life of the heart, there is only one of these curves which depicts its instantaneous pumping effectiveness.

ALTERATION OF THE LOAD AGAINST WHICH THE HEART MUST PUMP. It is quite obvious that the greater the resistance against which the heart must pump blood, the less effectively can it pump (171). Consequently, increased resistive load in either the pulmonary or systemic circulation decreases the cardiac output curve, while decreased resistive load increases the cardiac output curve. These effects are also illustrated in figure 2.

Obviously, cardiac load can vary through all differ-

ent degrees at different times. Therefore, once again a vast "family" of cardiac output curves is required to depict the effects of varying loads on the function of the heart-lung segment. This family of curves is almost identical with that which depicts the functional characteristics of the hypereffective versus the hypoeffective heart.

ALTERATIONS IN PRESSURE ON THE OUTSIDE OF THE HEART. The degree of filling of the heart is determined by the effective filling pressures of the cardiac chambers, that is, by the differences between the pressures inside the cardiac chambers and the pressure on the outside of the heart. Ordinarily, the heart is surrounded by the negative pressure of the intrathoracic cavity and this negativity contributes greatly to the effective filling pressure. However, at times the negative pressure becomes altered or completely lost. For instance, opening the chest immediately shifts the heart from negative pressure surroundings to zero pressure surroundings (atmospheric pressure). And, even more important, pericardial fluid (145, 157), pericardial constriction (25), intrapleural fluid, pneumothorax (186), or mediastinal compression can all cause intensive positive pressure on the outside of the heart, thereby markedly reducing the effective filling pressures of the cardiac chambers.

In circuit analysis, an increase in the external pressure on the heart is an extremely important consideration for the following very simple reason: The resultant changes in filling pressures are not compensated by simultaneous changes in pressure in the systemic circulation. As a consequence, venous return ordinarily becomes greatly reduced.

Figure 3 illustrates the effects of opening the chest and of cardiac tamponade on the cardiac output curves. Simply opening the chest shifts the entire curve approximately 5 mm Hg to the right because of loss of the normal 5 mm Hg negative pressure in the intrathoracic cavity. This means that for the heart to pump an equivalent amount of blood after opening the chest as before, the right atrial pressure must be increased 5 mm Hg, thus explaining the detrimental effect of opening the chest on blood flow in the circulation.

The lowest curve of figure 3 illustrates even more drastic depression of the cardiac output curve, this time caused by severe cardiac tamponade. Because in this condition the intrapericardial pressure rises as the heart fills to greater volumes, the curve is not simply shifted to the right as one might have expected, but its slope and its maximum value are also reduced,

FIG. 3. Cardiac output curves, showing the effect of opening the chest and of cardiac tamponade.

the degree, of course, depending upon the degree of cardiac tamponade.

SUMMARY OF FACTORS THAT AFFECT THE CARDIAC OUTPUT CURVES. From the above discussion of the different factors that affect cardiac output curves, we see that the curves fall into two simple patterns. First, any factor that increases the effectiveness of the heart as a pump or decreases the load against which it must pump will elevate the curves. Conversely, any factor that decreases the effectiveness of the heart as a pump or increases its load will depress the curves. The second pattern of cardiac output curves occurs when pressure on the outside of the heart alters the effective cardiac filling pressures. The greater the pressure outside the heart, the further to the right is the cardiac output curve shifted.

By keeping these basic principles in mind one can determine with relative accuracy what the cardiac output curve of any given heart under any given condition will be, but it must always be remembered that at any instant the pumping effectiveness of the heart is depicted by only a single cardiac output curve, not by a family of curves. With this discussion of cardiac output curves as a background, we can now proceed to the somewhat more complicated venous return curves which are the "complements" to the cardiac output curves.

Venous Return Curves

VENOUS RETURN CURVES AS COMPLEMENTS TO CARDIAC OUTPUT CURVES. Referring back to figures 2 and 3, one

sees that each cardiac output curve represents an infinite series of cardiac outputs over a range of right atrial pressures. However, it is obvious that the cardiac output at any given time can be only one value, not an infinite number of values. The next question that arises is, how does one determine where on the cardiac output curve the circulatory system will be operating at a given time? Obviously, if one can determine the right atrial pressure, he can then determine the cardiac output. However, the right atrial pressure, like the cardiac output, is a variable. For this reason, we must find some method to determine the right atrial pressure at the same time that we determine the cardiac output. A method for doing this is to analyze the systemic circulation in terms of right atrial pressure and flow, just as the heart-lung segment has been analyzed for right atrial pressure and flow. This time we use the term "venous return" for the flow, but we still use right atrial pressure as the opposite coordinate. If we remember that venous return equals cardiac output except for transient instantaneous differences, we see that we are using exactly the same coordinates for analyzing the characteristics of the systemic circulation as we have used for the heart-lung segment of the circulation. Once this is done, the curves depicting the respective functions of the two segments of the circulation can be plotted on the same coordinates, and the point at which the two curves cross provides a solution that gives the venous return, the cardiac output, and the right atrial pressure, all simultaneously (81).

METHOD FOR RECORDING VENOUS RETURN CURVES. To determine the effect of right atrial pressure on the return of blood from the systemic circulation to the heart, we must use one of three different procedures: 1) isolate the systemic circulation and use a controlled pump in place of the heart, 2) control the action of the heart itself by placing a controlled pump in place of one portion of the heart, or 3) make measurements of flows and pressures in different parts of the systemic circulation while artificially altering the pumping ability of the heart. In our laboratory, we have studied the effect of right atrial pressure on venous return using all these three different methods, in open-chest animals when using the first two methods (87, 96, 98, 99, 102, 103, 105) and in closed-chest animals when utilizing the third method (97). The results have been identical within the limits of experimental error. Furthermore, contrary to the effects on the cardiac output curve, opening the chest

does not significantly alter the effect of right atrial pressure on venous return.

Figure 4 illustrates one of the typical methods used to study venous return. This procedure substitutes an external perfusion circuit for the right heart. The right atrium is cannulated, and blood is pumped from this cannula through a system that includes *a*) a collapsible tube that can be raised or lowered to adjust the right atrial pressure, *b*) a heater used to maintain a normal blood temperature, *c*) a pump that always provides sufficient propulsive force to keep flowing through the circuit all the blood that is allowed to pass the collapsible tube, and *d*) a recording flowmeter, usually of the rotameter type. After passing through this external circuit, the blood is reinfused into the distal stump of the pulmonary artery. Thus, all the blood entering the right atrium must pass through this external circuit. This system allows continuous recording of the blood flow through the heart, which can be termed either "venous return" or "cardiac output." Indeed, even all the coronary blood flow, which empties into the right atrium, courses through this circuit. Furthermore, the pressure inside the collapsible tube automatically adjusts exactly to the atmospheric pressure; therefore, the right atrial pressure can be elevated or lowered and maintained at a very exact value, regardless of how much blood flows into the right atrium, by simply raising or lowering the collapsible segment.

Still another important feature of this system is that the right atrial pressure, except during periods of measurements, can be maintained at a negative value, thus allowing blood to flow from the extrathoracic veins into the right atrium with equally as much ease

as in the closed-chest animal. Therefore, in using this preparation, the circulatory system does not deteriorate, as is usually the case when the veins are cannulated (178), but, instead, will continue in an active state for many hours.

EFFECT OF RIGHT ATRIAL PRESSURE ON VENOUS RETURN—THE NORMAL VENOUS RETURN CURVE. Figure 5 illustrates the normal effect on venous return of increasing the right atrial pressure (96). Note that this curve, like the cardiac output curves discussed above, does not tell one exactly what the venous return will be, but tells instead what the venous return would be if the right atrial pressure were known. Furthermore, this venous return curve depicts the circulatory conditions at a given instant, but it can become considerably altered, as will be discussed below, from one instant to another. For this reason, all the different points along the curve must be measured under identical circulatory conditions. This has been difficult to do, because any time the venous return falls to subnormal values, circulatory reflexes immediately ensue, attempting to return the venous return back toward a normal value. In so doing, the venous return curve becomes greatly altered, which also will be discussed below. To prevent this, two different methods have been used to measure the venous return curve without altering systemic conditions by circulatory reflexes or by other circulatory changes during the course of measurement. First, venous return curves have been measured in animals subjected to total spinal anesthesia, which abrogates all circulatory reflexes. However, to determine the normal venous return curve, a drip of epinephrine or norepinephrine is administered to the animal to return the vasomotor tone back to normal prior to making the measurements necessary to establish the curve.

FIG. 4. External perfusion system in which a pump controls the activity of the heart. Using this external system it is possible to raise and lower the right atrial pressure at will while studying the effect of right atrial pressure on venous return.

FIG. 5. The normal venous return curve.

The second method for establishing the normal venous return curve has been to determine different points along the curve intermittently by suddenly elevating the right atrial pressure and making venous return measurements within the next 5 to 7 sec before circulatory reflexes can take place. Then the circulation is returned to normal, and after a reasonable control period another intermittent measurement is made.

The venous return curves recorded by these two different procedures have been identical. Furthermore, venous return curves have been recorded in closed-chest animals in which a special occluding system has been surgically placed around the pulmonary artery so that the pulmonary artery could be occluded to any desired degree (97). Then, using especially the intermittent procedure, points along the venous return curve were established. The results agree with the measurements established when using the above two procedures.

The venous return curve of figure 5 is the average curve, recorded in approximately 100 separate dogs anesthetized with sodium pentobarbital, and then extrapolated on a weight basis to the 12-kg dog. Several features of this curve deserve special comment.

First, when the right atrial pressure becomes more negative than 0 to -4 mm Hg, a further increase in the negativity of the right atrial pressure does not cause a further increase in venous return. In other words, the venous return curve reaches a "plateau." The cause of this effect is the well-known collapse factor in veins (88, 112). One can actually see the veins entering the thoracic cavity begin to collapse when the right atrial pressure becomes negative with respect to atmospheric pressure. Furthermore, measurements in the veins immediately beyond the collapsed points show that these veins all have approximately 0 mm Hg pressure in them regardless of how low the right atrial pressure falls. Thus, the collapse factor effectively sets the venous pressure of the blood leaving the systemic circulation almost exactly at 0.

The second important point in relation to the venous return curve is that elevation of the right atrial pressure above 0 causes a very rapid decrease in return of blood from the systemic circulation (98). On the average, for each mm Hg rise in pressure above 0, the venous return decreases 14 per cent, and it reaches zero when the right atrial pressure has risen to approximately $+7$ mm Hg in "areflex" dogs.

The third important point is that when venous return reaches zero, the right atrial pressure at this

level is equal to the mean systemic pressure (98). The mean systemic pressure is the pressure in the systemic circulation that is measured if the root of the aorta and the large systemic veins entering the heart are suddenly occluded and all pressures in the systemic circulation are brought instantaneously to equilibrium. That is, when blood flow ceases absolutely in the systemic circulation, the pressures in all its segments become equal. Therefore, the right atrial pressure becomes equal to the pressure everywhere in the systemic vessels. This equilibrium pressure is the mean systemic pressure.

The fourth point of major significance in relation to the venous return curve is the almost complete linearity of the venous return curve in the range between 0 right atrial pressure and the mean systemic pressure level. That is, the venous return is approximately proportional to the difference between mean systemic pressure and right atrial pressure ($P_{ms} - P_{ra}$). This difference is called the "pressure gradient for venous return" (81), and it is an important concept in establishing the forces that lead to the flow of blood toward the heart. This will be seen below, especially in relation to alterations in systemic resistances, for when there is no pressure gradient for venous return, there will be no venous return to the heart regardless of the changes in systemic resistances.

EFFECT OF PERIPHERAL RESISTANCE ON VENOUS RETURN. Figure 6 illustrates the effect on the venous return

FIG. 6. Effect on the venous return curve of changing the peripheral resistance. Note that the mean systemic pressure remains constant at approximately 7 mm Hg.

FIG. 7. Effect on the venous return curve of suddenly opening large bilateral femoral A-V fistulae.

curve of changing the systemic resistance from normal (87). Note that the venous return is exactly zero in the case of each of these three curves when the right atrial pressure is equal to the mean systemic pressure. That is, when there is no pressure gradient for venous return, there is likewise no flow toward the heart. Yet, when the right atrial pressure falls to some value below the mean systemic pressure, then a pressure gradient does exist for forcing blood toward the heart, and the return of blood is inversely proportional to the resistance. The greater the resistance, the less is the return of blood to the heart, and the less the resistance, the greater is the venous return. Thus, figure 6 shows the normal venous return curve, a venous return curve in which the resistances throughout the systemic circulation are approximately one-half normal, and a venous return curve in which the resistances are approximately two times normal.

Figure 7 illustrates a typical experiment in which peripheral resistance was suddenly changed while all other conditions of the circulation were kept as nearly constant as possible (103). In this instance two large femoral A-V fistulae were suddenly opened so that the total peripheral resistance was decreased to approximately 60 per cent of the control value. Circulatory pressures remained exactly constant. Note that the study depicts precisely the same effects as those illustrated in the previous figure but this time showing a typical and actual experimental study

It should not be supposed, however, that increasing the resistance to blood flow in the arteries affects venous return equally as much as increasing the resistance in the veins. Indeed, for a given increase in venous resistance, the venous return decreases approximately eight times as much as when the arterial resistance is increased the same amount. This was illustrated by a comparative study in which arterial resistance was increased by injecting microspheres into the arterial system and venous resistance was increased by progressive occlusion of all the large veins emptying into the right atrium (87). Figure 8 illustrates the difference between these two effects, the upper curve showing that the total peripheral resistance could be increased by arterial embolization to as much as 400 to 500 per cent of control values before the venous return decreased a great amount. On the other hand, increasing the total peripheral resistance only 30 per cent by the method of venous compression decreased the venous return to one-half normal.

The cause of this difference between venous resistance and arterial resistance is that the arterial system proximal to the arterioles has very little capacitance (DV/DP) in relation to the total capacitance of the systemic circulation proximal to the venous constriction at the outflow of the veins into the heart (89). Because of the small storage ability of the arteries for blood, increasing the resistance at the arterioles elevates the arterial pressure almost as

FIG. 8. Effect on venous return of increasing the total peripheral resistance when the resistance is increased in three different ways: 1) by injecting microspheres into the arteries to increase arterial resistance, 2) by constricting the inflow veins to the heart, and 3) by a combination of these two procedures. [From Guyton *et al.* (87).]

much as the resistance rises, and the arterial pressure then simply forces the blood on past the resistance. On the other hand, constricting the veins where they empty into the heart causes the pressure in the veins to rise only a few mm Hg because of the great storage capacity of the veins. This small rise in venous pressure is far too little to overcome the increasing resistance, and, as a consequence, the venous return becomes tremendously depressed. Therefore, venous resistance affects venous return to the heart many times as much as arteriolar or arterial resistance of the same magnitude.

EFFECT OF MEAN SYSTEMIC PRESSURE ON VENOUS RETURN. Basically the mean systemic pressure is the resultant of the ratio of *a*) the blood volume to *b*) the ability of the circulatory system to hold blood. As the blood volume increases, the mean systemic pressure remains essentially zero until the blood barely begins to distend the blood vessels. But, once this point has passed, any further increase in blood volume increases the mean systemic pressure directly in proportion to the additional amount of blood injected into the circulation, the mean systemic pressure rising approximately 1 mm Hg for each 2 per cent increase in blood volume (86). Thus, it can be seen that very small changes in blood volume can cause relatively large changes in mean systemic pressure and, as a consequence, can have a marked effect on venous return unless other circulatory compensations prevent this.

Only a few measurements of mean systemic pressure have ever been made, for this requires instantaneous stoppage of the circulation and then rapid equilibration of the pressures in all segments of the systemic circulation before any blood can leave or before circulatory reflexes or other factors can change the vascular distensibility. In our laboratory, we have measured this pressure a few times by suddenly constricting the aorta and pulmonary arteries (138), utilizing devices implanted several weeks previously in the thoracic cavity to cause the constrictions. These pressure measurements showed a normal mean systemic pressure of almost exactly 7 mm Hg.

Far more measurements have been made of the mean circulatory pressure (101, 105, 180, 182) than of the mean systemic pressure; approximately 1000 such measurements have been made in our laboratory. Since the mean systemic pressure is of such extreme importance in determining venous return to the heart, the few measurements of mean systemic pressure have been compared with measurements of

mean circulatory pressure. In all instances, the mean systemic pressure has been almost identical with the mean circulatory pressure except in the case of extreme engorgement of the pulmonary circulation, and even here the difference has been only 1 mm Hg or so. Therefore, insofar as venous return from the systemic circulation is concerned, one can consider the mean systemic pressure and mean circulatory pressure to be almost identical.

Measurements of mean circulatory pressure can be made very easily by electrically fibrillating the heart with 60-cycle current applied to needle electrodes in the anterior chest wall at approximately 50 v. Studies have demonstrated that all pressures of significance in the measurement of mean circulatory pressure come to equilibrium within only a few seconds after cardiac fibrillation begins, except for the pressures of the systemic arterial chamber and the systemic venous chamber. Therefore, immediately after fibrillation of the heart begins, arterial blood is pumped from a catheter lying in the descending aorta and thence through another catheter into the inferior vena cava. After only 3 to 5 sec, the pressures in these two chambers are brought to equilibrium and the mean circulatory pressure measured. During the next few seconds the heart is defibrillated by passing 4 to 10 amperes of 60-cycle alternating current at 440 v for $\frac{1}{10}$ sec directly through the chest anteroposteriorly (104). After 2 to 3 min of recovery, the animal returns to essentially normal circulatory conditions.

Figure 9 illustrates the typical effect on the venous

FIG. 9. Effect on the venous return curve caused by changes in mean systemic pressure.

return curve caused by altering the mean systemic pressure. Note that when the mean systemic pressure is increased from the normal value of 7 mm Hg up to 14 mm Hg the curve is shifted to the right and its plateau becomes approximately twice as high as normal. Conversely, when the mean systemic pressure is decreased to 3.5 mm Hg, which is one-half normal, the curve is shifted to the left, and the plateau becomes reduced to one-half normal. Since the flow of blood to the heart is proportional to the pressure gradient for venous return, which in turn is equal to the mean systemic pressure minus the right atrial pressure, one can see that any increase in mean systemic pressure causes a corresponding increase in venous return at any given right atrial pressure. Likewise, any decrease in the mean systemic pressure will cause a corresponding decrease in venous return at all right atrial pressures.

Figure 10 depicts venous return curves in a series of normal dogs and then again in the same dogs after an average infusion of 200 ml of blood and also after hemorrhage of 122 ml (99). Note that the normal mean systemic pressure was approximately 7.7 mm Hg, that this rose to 11.3 mm Hg in the infused dog, and that it fell to 4.7 mm Hg in the hemorrhaged dog. This experiment illustrates typical shift of the venous return curves to the right as the blood volume increases, thereby increasing the mean systemic pressure.

Changes in the distensibility of the vascular system or changes in the pressure on the outside of the vessels can alter the mean circulatory pressure in exactly the same manner as can alterations in blood volume. These changes include *a*) increased vaso-

motor tone, caused either by sympathetic stimulation or by infusion of sympathomimetic drugs; *b*) pressure on the abdomen, which compresses large intra-abdominal blood reservoirs; *c*) increased intrathoracic pressure, which compresses the blood reservoirs of the chest; and *d*) increased interstitial fluid volume, which causes pressure on the outside of blood vessels throughout the body. In normal circulatory adjustments the most important of these is the effect of vasomotor tone on the mean systemic pressure.

Figure 11 illustrates the average results from 11 typical experiments in dogs in which the degree of vasomotor tone was altered from the minimal level up to almost the maximal level (95). This shows the typical effects one would expect when the mean systemic pressure is elevated, that is, progressive shift of the venous return curves to the right as the vasomotor tone is increased.

One might have expected the administration of a sympathomimetic drug to cause increased resistance to blood flow toward the heart as well as to increase the mean circulatory pressure. This was not evident from these studies, for the venous return curves did not decrease in slope as the rate of epinephrine injection was increased. On second thought, one can understand why this was true. When vasomotor tone is increased throughout the circulation while the blood volume remains constant, pressures everywhere in the circulation will tend to rise because of tightening of the vessels around the blood. But, if any single segment of the circulation constricts, some other segment of the circulation must dilate. On the average, then, for every constriction that occurs in the systemic circulation following the injection of

FIG. 10. Effect of increasing or decreasing the blood volume on the venous return curves. Total spinal anesthesia was instituted to prevent cardiovascular reflexes during the course of the experiment. [From Guyton *et al.* (99).]

FIG. 11. Effect of different rates of epinephrine injection on the venous return curves. Note that the principal effect is to increase the mean systemic pressure. [From Guyton *et al.* (95).]

epinephrine, as depicted in the experiments of figure 11, there had to be equal dilatation somewhere else. Indeed, measurements have shown that, as the arterioles constrict under these conditions, there is a tendency for the veins to dilate even though the walls of the veins do tighten to a very great extent (55). This elevates the mean systemic pressure but does not increase the resistance to blood flow from the systemic vessels toward the heart. In essence, then, we can say that an increase in vasomotor tone affects venous return principally by increasing the mean systemic pressure, and, usually, an increase in vasomotor tone does not increase the average resistance that opposes the return of blood to the heart.

SUMMARY OF FACTORS THAT AFFECT THE VENOUS RETURN CURVES. Basically, there are only two different patterns of changes in venous return curves, those that result from *a*) changes in resistance in the systemic circulation, and *b*) changes in the mean systemic pressure. Figure 6 depicts the pattern of venous return curves that results from alteration of vascular resistance, while figure 9 illustrates the curves that result from alteration of mean systemic pressure.

Any factor that alters resistance, whether this be a localized or generalized alteration, will correspondingly alter the venous return curve. However, alteration of the venous resistance affects venous return far more drastically than alteration of the arterial resistance.

The factors that affect the mean systemic pressure can be divided into two main groups: 1) those that affect the blood volume, and 2) those that affect the ability of the circulatory system to hold blood. The two most important factors of all that affect mean

systemic pressure are blood volume itself and changes in vasomotor tone.

The interrelationships of all these different factors on the return of blood to the heart can be expressed mathematically by the following formula (98):

$$VR = \frac{P_{ms} - P_{ra}}{\frac{R_v C_v + (R_v + R_a) C_a}{C_v + C_a}}$$

In this formula VR is venous return, P_{ms} is mean systemic pressure, P_{ra} is right atrial pressure, C_v is capacitance of the veins, C_a is capacitance of the arterial tree, R_v is the average resistance to blood flow from the veins to the heart, and R_a is the resistance from the arterial tree to the venous tree. This formula shows that venous return is approximately proportional to the mean systemic pressure minus right atrial pressure, which has been called the "pressure gradient for venous return," while, on the other hand, venous return is inversely proportional to the resistances in the systemic circulation. The capacitances in the formula are constants for any given animal, and they determine the relative importance of arterial resistance versus venous resistance. In the normal animal a given change in venous outflow resistance affects venous return approximately eight times as much as the same change in arterial resistance (87).

Equating the Venous Return and Cardiac Output Curves

If one understands the different factors that affect venous return and cardiac output curves, he can readily determine the approximate effects of any given circulatory change on each of these two types

FIG. 12. Equating of a normal cardiac output curve and a normal venous return curve for a 12-kg dog.

of curves. Then by plotting the two curves on the same coordinates, as shown in figure 12, the equations represented by the separate curves can be solved (81). Figure 12 illustrates the equating of a normal venous return curve with a normal cardiac output curve, as depicted for the 10-kg dog. Note that there is only one single point at which the flows and the pressures for the two curves are equal, and this point is called the "equilibrium point." It represents the solution to our graphical analysis, depicting in figure 12 that this particular dog at this particular time has a cardiac output of 1200 ml per min, a venous return also of 1200 ml per min, and a right atrial pressure of -2 mm Hg (referred to the level of the tricuspid valve).

Looking once again at figure 12, let us assume that an extra quantity of 25 ml of blood is suddenly injected into the right atrium. This would raise the right atrial pressure to approximately $+4$ mm Hg, and, as depicted by the venous return curve, the elevated right atrial pressure would decrease the venous return to approximately 500 ml per min. On the other hand, the high right atrial pressure would cause the cardiac output, as depicted by the cardiac output curve, to rise to approximately 2000 ml per min. Thus, a disparity of 1500 ml per min develops between venous return and cardiac output so that far more blood is pumped out of the heart than returns to it. Therefore, within the next three to six heartbeats, the right atrial pressure falls back to the level of -2 , thus causing the venous return to rise up to 1200 ml and the cardiac output to fall to 1200 ml. In other words, within a few seconds, equilibrium will be re-established whenever venous return and cardiac output deviate from each other (35).

EFFECT OF SYMPATHETIC STIMULATION ON VENOUS RETURN, CARDIAC OUTPUT, AND RIGHT ATRIAL PRESSURE. Using the same principles for equating venous return and cardiac output curves as depicted in figure 12, we can now show in figure 13 the effect of strong sympathetic stimulation on venous return, cardiac output, and right atrial pressure. The dashed curves of the figure illustrate the normal curves. Then, suddenly, sympathetic stimulation changes both the venous return and cardiac output curves to the respective solid curves (95). Note that the venous return curve shifts far to the right and upward because of an increase in "mean systemic pressure," and the cardiac output curve shifts upward, as is characteristic of a hypereffective heart. These two curves equate at an entirely new point, the new equilibrium point occurring at a right atrial pressure of -3 mm Hg and a cardiac output and venous return of 1800 ml per min.

This analysis of the effects of sympathetic stimulation agrees with the typical experimental result found when the sympathetics are stimulated throughout the body, that is, a mild to moderate increase in venous return and cardiac output and usually a slight decrease in right atrial pressure (169). Almost

FIG. 13. Effect of sympathetic stimulation on the venous return and cardiac output curves, showing an increase in cardiac output and venous return and a decrease in right atrial pressure.

exactly the opposite effects occur when vasomotor tone is greatly reduced throughout the body by the administration of nitrites (195) or ganglion-blocking agents (189). Likewise, pooling of blood in the lower part of the body when one stands (5, 76, 142-144, 175, 184, 196) or sequestration of blood in the limbs by the application of tourniquets (59, 193) reduces the venous return and cardiac output in a closely similar manner.

EFFECT OF MUSCULAR EXERCISE ON VENOUS RETURN, CARDIAC OUTPUT, AND RIGHT ATRIAL PRESSURE. Figure 14 illustrates an analysis of the circulation during exercise, showing changes in both the cardiac output and venous return curves. The cardiac output curve is elevated as a result of *a*) sympathetic stimulation of the heart, and *b*) inhibition of the vagi to the heart, thus giving a cardiac output curve of a hypereffective heart.

Three different factors cause the observed alterations in the venous return curve. First, tightening of the musculature throughout the body, particularly

FIG. 14. Effect of exercise on the venous return and cardiac output curves, showing that the new curves equate at greatly elevated venous returns and cardiac outputs. Also, the right atrial pressures are still close to zero mm Hg.

tightening of the abdominal musculature, causes an instantaneous increase in mean systemic pressure of several millimeters of mercury (100). Second, sympathetic stimulation causes considerable increase in mean systemic pressure (101). Third, the blood vessels of the musculature are likely to become markedly dilated, thus decreasing the resistance to blood flow through the systemic circulation (12); this, in turn, increases the slope of the venous return curve (87). Thus, we find that in moderate exercise the cardiac output and venous return may be increased to two or more times normal, and the right atrial pressure will still be only slightly elevated (14, 169, 174). On the other hand, in severe exercise, the heart is then often taxed to its limit so that the right atrial pressure rises considerably as depicted by the highest equilibrium point in the figure. In an animal or human being that has been thoroughly trained for athletics, the cardiac output curve of the heart can rise to one and one-half to two times that depicted in figure 13, thus giving as much as a five- to sevenfold increase in cardiac output without an elevation of right atrial pressure above zero.

Here, again, it is quite evident that simultaneous analysis of the function of the heart and of peripheral circulatory factors is needed to ascertain the integrated effects of exercise on venous return, cardiac output, and right atrial pressure (10, 39, 50, 169, 177, 188).

EFFECT OF RAPID TRANSFUSION ON VENOUS RETURN, CARDIAC OUTPUT, AND RIGHT ATRIAL PRESSURE. Figure 15 depicts the effects of rapidly infusing an animal with whole blood. The immediate effect stems mainly from an increase in mean systemic pressure (99)—in this instance from 7 mm Hg to 11.5 mm Hg. However, the increased blood volume also distends the vessels of the systemic circulation, thus decreasing the peripheral resistance and therefore increasing the "slope" of the venous return curve. In the case of the heart, circulatory reflexes, especially the pressoreceptor reflex, actually weaken the heart because the excess blood volume tends to elevate arterial pressure, thereby initiating inverse reflexes. As a consequence, the cardiac output curve decreases very slightly. The net result, as depicted by the equilibrium point, is a moderate increase in venous return and cardiac output and a very marked rise in right atrial pressure, which are effects that have been observed many times by many different investigators (66-69, 115, 183). This figure and the previous one illustrates that the relationship between right atrial

FIG. 15. Effect of rapid transfusion of blood on venous return and cardiac output curves, showing the result to be an elevated venous return and cardiac output and also a considerably elevated right atrial pressure.

pressure and cardiac output is not always even directionally the same (169), for in some circulatory conditions the cardiac output rises while the right atrial pressure falls; at other times, as in figure 15, the right atrial pressure can rise very greatly while the venous return and cardiac output change relatively little.

EFFECT OF SHOCK ON VENOUS RETURN, CARDIAC OUTPUT, AND RIGHT ATRIAL PRESSURE. Figure 16 depicts by the dashed curves the normal equating of venous return and cardiac output curves and then by the solid curves the effects immediately after hemorrhage in the so-called compensated stage of shock. In this instance, the hemorrhage has reduced the mean systemic pressure considerably, shifting the venous return curve to the left (99). Immediately, however, circulatory reflexes have become active, causing the heart to become hypereffective and greatly elevating the cardiac output curve. The decreased blood volume also causes the slope of the venous return curve to decrease. Therefore, for two reasons, 1) decreased mean systemic pressure, and 2) increased resistance to venous return, the venous return curve is shifted to the left, and its plateau is reduced. Therefore, the venous return and the cardiac output curves equate

FIG. 16. Effect of shock on the venous return and cardiac output curves, showing in the early compensated stage of shock a low venous return and cardiac output but also a greatly depressed right atrial pressure (point A). In irreversible shock the cardiac output becomes greatly depressed as illustrated by the dash-dot curve; venous return and cardiac output become greatly reduced while the right atrial pressure rises (point B).

at point A, the cardiac output and venous return falling to about one-half normal and the right atrial pressure falling to -5 mm Hg. These are typical effects observed following acute hemorrhage (90, 160, 161, 167). Very similar effects occur in persons with vasomotor collapse except that the partial reflex compensation which occurs following hemorrhage is absent (147).

In the irreversible stage of shock an entirely different situation ensues, because the heart then begins to deteriorate. This has been shown especially by the work of Crowell (92), but also by measurements made in Wiggers' laboratory (61, 150, 197, 198) and by Remington (161). The cardiac output curve falls to the lower curve of the figure, and the new equilibrium point is now point B. Thus, the venous return and cardiac output fall to a still lower value while the right atrial pressure begins to rise; these are typical events in the irreversible and terminal stage of shock. As a result of this additional decrease in cardiac output, the heart deteriorates still more, and a vicious cycle of cardiac deterioration develops, causing a progressive rise in right atrial pressure and a progressive fall in venous return and cardiac output.

EFFECT OF OPENING THE CHEST ON VENOUS RETURN, CARDIAC OUTPUT, AND RIGHT ATRIAL PRESSURE. Figure 17 illustrates the changes that occur in the circulation when the chest is opened. The dashed curves represent the normal circulatory conditions and then the long dashed curve represents the immediate effects on the cardiac output curve caused by opening the chest. The new equilibrium point, point *A*, shows that the cardiac output falls to approximately two-thirds normal and the right atrial pressure rises immediately from -2 mm Hg to $+2$ mm Hg. However, within approximately 30 sec to 1 min, circulatory reflexes, especially pressoreceptor reflexes, cause *a*) the cardiac output curve to rise to that depicted by the solid curve, and *b*) the venous return curve to shift to the solid venous return curve. These two curves equate at point *B* which depicts the final effects of opening the chest on cardiac output, that is, only a little decrease in cardiac output (22) but a considerable rise in right atrial pressure. One might immediately ask, therefore: Does opening the chest have any significant detrimental effect on the circulation? The answer to this is very definitely "yes", for the following reasons: In order for the venous return and cardiac output to recompensate essentially to normal, strong circulatory reflexes will have been set into play. Thus, an animal with his chest open has already utilized a major share of his circulatory reflex power simply to compensate for opening the chest. Now, the reserve reflex power left to compen-

FIG. 17. Effect of opening the chest on the venous return and cardiac output curves, showing by point *A* the immediate effect and point *B* the effect after circulatory reflexes ensue.

sate for other circulatory stresses, such as hemorrhage, has been greatly reduced. Therefore, it can be said that the "circulatory reserve" has been considerably reduced as a result of the opened chest. This analysis, therefore, explains why the cardiac outputs of open-chest animals are normally only slightly below those of normal animals, but it also explains why animals and human beings under these conditions can withstand far less circulatory stress than can the normal (42).

EFFECT OF MYOCARDIAL DAMAGE ON VENOUS RETURN, CARDIAC OUTPUT, AND RIGHT ATRIAL PRESSURE. Figure 18 illustrates the progressive changes that occur in the circulation following sudden acute myocardial damage to both sides of the heart approximately equally. The short dashed curves illustrate normal equilibrium conditions. Then, suddenly, the heart becomes severely damaged as a result of acute myocardial infarction, reducing the cardiac output curve to that depicted by the long dashes. As a result, the new equilibrium point is now approximately one-third normal, and the right atrial pressure has risen to $+4$ mm Hg. However, these conditions do not obtain for a prolonged period of time because autonomic reflexes, mainly sympathetic, cause immediate compensations within the next 30 sec to 2 min (2-4, 40, 80, 152). At the end of this period, the sympathetic stimulation will have increased the cardiac output

FIG. 18. Effect of acute myocardial infarction and subsequent stages of recovery on the cardiac output and venous return curves. The sequence of events is explained in the text.

and venous return curves up to those depicted by the dashes and dots. Therefore, within 2 min, the venous return and cardiac output will have returned to approximately two-thirds normal, and the right atrial pressure will have risen another 2 mm Hg up to +6 mm Hg. But, even this is an abnormally low cardiac output which is still insufficient to supply all the tissues of the body with adequate amounts of blood. Furthermore, there is intense sympathetic vasoconstriction throughout the circulatory system during this period of time as well as sometimes a decreased arterial pressure; the intense sympathetic vasoconstriction (134) and the decreased arterial pressure (135) both decrease renal output. Furthermore, the semishock state that exists at this stage causes the adrenal glands to secrete large quantities of aldosterone. This, in turn, promotes rapid reabsorption of sodium from the renal tubules, associated also with rapid reabsorption of water (48). The net effect on the kidneys, therefore, is to reduce renal output greatly or, at times, even to stop renal output completely. Over a period of the next few days, fluid is progressively retained in the circulatory system, thus shifting the venous return curve in figure 18 further and further to the right (99, 105). The solid venous return curve depicts approximately that which will obtain after a week or so of fluid retention.

Simultaneously with the changes that take place in the venous return curve, the heart will also be changing. If the infarction is an uncomplicated one and recovery from the infarction begins immediately, then the cardiac output curve of figure 18 will progressively rise. The solid cardiac output curve depicts approximately that which one would expect after a week of recovery. As illustrated by the point at which the solid cardiac output curve equates with the solid venous return curve, we find that the cardiac output and venous return will have now returned almost completely to normal but that the right atrial pressure again will have risen another 2 mm Hg. This is characteristic of the chronic stage of congestive heart failure, that is, the cardiac output may be normal or slightly below normal, but the venous pressures are essentially always greatly elevated.

Another effect that occurs as the cardiac output approaches normal is that the degree of sympathetic activity throughout the body also gradually becomes reduced toward normal. Furthermore, the body is no longer in a shocklike state so that the output of aldosterone also becomes reduced. As a consequence, renal output once again returns toward normal, thus preventing further retention of fluid. Therefore, the circulatory system has now reached a new steady

state, with the cardiac output and venous return essentially normal, renal output once again essentially normal, but the right atrial pressure considerably elevated.

It should be noted again that the analysis illustrated in figure 18 is that for myocardial damage affecting both ventricles approximately equally. The course of events depicted by the dotted line is typical of that normally observed following acute generalized myocardial infarction (13, 71, 73, 75, 106-108, 121, 162, 163, 166). We shall see that the more complicated graphical analysis presented later in the chapter is much more satisfactory than the simple graphical analysis when one side of the heart fails to a greater extent than the other side.

ANALYSIS OF DECOMPENSATION AND COMPENSATION IN CONGESTIVE HEART FAILURE. Figure 19 illustrates an analysis of decompensation in severe cardiac failure. This shows by the two dashed curves the analysis for the normal circulatory system in a normal 10-kg dog. Then, at the bottom of the graph, it shows the typical cardiac output curve for a severely damaged heart after all sympathetic reflexes and all recovery that are possible have taken place (38). If we assume that the cardiac output curve suddenly falls from the normal down to this depressed curve, then we find that the cardiac output immediately falls to point *A*, about two-fifths normal, with a right atrial pressure of approximately +4 mm Hg. This cardiac output is far too little to cause normal renal function, and, for the same reasons discussed above, renal output becomes severely depressed. As a result, fluids are retained in the body, and the mean systemic pressure progressively rises, shifting the venous return curves to the right and progressively elevating their plateaus. Thus, during the ensuing days, with the progressive retention of fluid, the equilibrium points in figure 19 proceed to *B*, *C*, *D*, *E*, *F*, and *G*. It is especially interesting that cardiac output curves of severely damaged hearts do not rise to a plateau but, instead, rise to a peak and then begin to descend (117). Therefore, after the process of decompensation has proceeded past the peak at point *E*, further retention of fluid causes a reduction in cardiac output rather than an increase.

The significant factor in decompensation is that even at its greatest peak, the cardiac output curve never reaches the necessary cardiac output level required to re-establish normal renal function. Consequently, fluids continue to be retained indefinitely until death of the animal.

FIG. 19. Analysis of decompensated heart disease, showing a greatly depressed cardiac output curve and a progressive shift of the venous return curves to the right until death occurs, as explained in the text.

Figure 20 depicts recompensation of the animal that had been almost dead from decompensated heart disease. The lower curve illustrates a cardiac output curve of a decompensated heart, showing that after a period of time the venous return curve had already reached the far right curve with equilibrium occurring at point A. Then, upon instituting appropriate treatment, such as the administration of digitalis (117), the heart becomes considerably stronger, and the cardiac output curve rises to the upper curve. If this rise is relatively rapid, the venous return curve will not be immediately affected. Therefore, the new equilibrium point becomes point B, which represents a cardiac output greater than that required for normal renal function. As a consequence, the output of urine now becomes actually far greater than normal, which is a well-known effect of digitalis when a decompensated state is converted into a compensated state. The output of urine causes a decrease in mean circulatory pressure and a progressive shift in the venous return curves toward the left. Thus, during the ensuing days, the equilibrium points in figure 20 shift from point B to C, to D, and finally E. At point E the venous return curve becomes stable because now the cardiac output has fallen back to a value that is just sufficient to maintain a renal output equal to the daily intake of fluid and salts. One can see that we now have three different curves equating with each other, the cardiac output curve, the venous return curve, and a straight line which is a curve representing the level required for normal renal function. It is where these three

FIG. 20. Analysis of recompensation after a bout of cardiac decompensation. The lower cardiac output curve represents the decompensated heart and the upper curve the recompensated heart. The sequence of events is explained in the text.

curves equate that the circulatory system finally establishes its steady-state equilibrium.

A heart can also be recompensated without increasing the cardiac output curve at all but simply by lowering the level required for normal function. For instance, in figure 20, if this were lowered down to a value of 700 ml per min, then point A would be approximately 100 ml per min greater than the level required for normal renal function. As a result fluid

would be lost and the venous return curves would proceed toward the left. This would continue until the cardiac output should fall to 700 ml per min, which would be the equilibrium point for the three different curves. The method by which this third curve, the level required for normal renal function, can be lowered is by administration of a diuretic or by drastic reduction of fluid and salt intake. Under either of these conditions the kidneys can then put out an amount of fluid equal to the daily intake despite the fact that the cardiac output is greatly reduced. Thus, the animal is kept from dying as a result of decompensation, and over a period of time its heart can perhaps recover or at least its life can be saved by continual adherence to a strict diuretic and fluid regimen.

ANALYSIS OF EFFECTS RESULTING FROM CHANGES IN VASCULAR RESISTANCE. The simplified graphical approach can also be used to analyze the effect of vascular resistance changes resulting from several different causes. For instance, the effects of anemia and polycythemia have been studied (102), and the results of the analyses are in accord with the experimental findings in these conditions (60, 109, 164, 176). Second, an analysis for A-V fistulae (104) also accords with the often repeated findings in these conditions (43, 116, 140, 148, 173). Third, a graphical analysis showing a very detrimental effect on venous return of increasing venous resistance (87) is in accord with many studies which have demonstrated that relatively slight venous constriction can cause either shock in the acute situation (63) or peripheral congestion in the chronic preparation (26).

A MORE COMPLEX GRAPHICAL ANALYSIS OF VENOUS RETURN, VENTRICULAR OUTPUTS, AND ATRIAL PRESSURES

The simplified graphical analysis which has just been presented is ordinarily quite satisfactory for analyzing the effects of most circulatory stresses on the circulation except when the stresses involve an imbalance between the left and right hearts. Such imbalances can result from unilateral cardiac failure or unilateral excess load on the heart. To determine the effects of these unilateral disturbances on the circulation, we now need to analyze the functions of all the four different segments illustrated in figure 1, all at the same time, that is, of the systemic circulation, the right heart, the pulmonary circulation, and the

left heart. Then all of these must be equated against each other. To do this we can proceed by pointing out, first, that the analyses of right heart venous return and right ventricular output are approximately the same as the analyses for the entire heart-lung segment. Therefore, right heart function, for practical purposes, can be depicted by the usual simplified analysis which has already been presented.

Also, the analyses for the pulmonary circulation and the left heart obey identically the same principles as those already discussed for the systemic circulation and right heart, though the quantitative values are entirely different. Figure 21 illustrates a typical analysis of venous return in the pulmonary circulation and also of the ventricular output of the left heart. Note that the left atrial pressure scale has been greatly shortened in relation to the right atrial pressure scale used in previous figures. The reason for this is that in later figures we will wish to use this analysis for the left heart in association with analyses for the right heart. When blood is shifted from the systemic circulation to the pulmonary circulation, the mean pulmonary pressure rises approximately 7 mm Hg for each 1 mm Hg fall in mean systemic pressure (138, 139, 146). Therefore, in the following equating procedures the scale for right atrial pressure will in all instances be seven times as great as the scale for left atrial pressure.

FIG. 21. Analysis of pulmonary venous return to the left heart and output from the left ventricle, illustrating the equating of these with each other in the steady-state condition.

In order to equate the events that take place in the left heart with those that take place in the right heart, we now need to transpose the direction of the scale for left atrial pressure. Figure 22 illustrates this transposition, showing now the left atrial pressure rising from right to left rather than from left to right.

FIG. 22. Transposition of the curves illustrated in fig. 21. This transposition allows the left heart analysis to be correlated with the right heart analysis in the following figures.

FIG. 23. Simultaneous analysis of left and right heart function, showing that in the steady state the venous returns and outputs of the two sides of the heart are all in equilibrium with each other.

Finally, we superimpose the analysis for the left heart onto a simultaneous analysis for the right heart, as shown in figure 23. In this superimposition, we place the left atrial and right atrial pressure scales so that the 7 mm Hg level of one coincides with the 7 mm Hg level of the other. The reason for this is that our preliminary measurements of mean pulmonary pressure show it to be almost identical in the normal state with the mean systemic pressure, that is, almost exactly 7 mm Hg. Now, we can explain the composite analysis of the two sides of the heart.

Note in figure 23 that the right ventricular output curve and the right ventricular venous return curve equate at the 1200 ml per min level. Likewise, the left ventricular output curve and the left ventricular venous return curve also equate at this same level. Therefore, under normal circumstances the two venous returns and the two ventricular outputs are all equal to each other, and the circulation is in a steady state, without any momentary transference of blood from one of the circulatory segments to another.

BALANCE OF THE TWO VENTRICULAR OUTPUTS WITH EACH OTHER. Proceeding to figure 24, we see the normal situation again depicted by the solid curves. However, the dotted venous return curves represent a situation in which excess blood has momentarily been transferred from the pulmonary circulation to the systemic circulation. Note especially that the two venous return curves intersect the zero venous return

FIG. 24. An analysis showing the manner in which the two sides of the heart automatically balance their outputs. The sequence of events is explained in the text.

level at the same point, and this point represents the mean systemic pressure on the right atrial pressure scale and the mean pulmonary pressure on the left atrial pressure scale. Thus, the mean systemic pressure has risen from 7 mm Hg to 7.5 mm Hg, and this has caused the right ventricular output to rise to point *B*, a value about 10 per cent above normal. On the other hand, the shift of blood out of the lungs has decreased the mean pulmonary pressure from 7 mm Hg to 3.5 mm Hg, thus shifting the left ventricular venous return curve to the right and decreasing the left ventricular output to point *B'*, an output 40 per cent below normal. This represents a disparity of outputs between the two ventricles of 2 to 1 with far greater amounts of blood being pumped by the right heart than by the left heart. As a consequence, a major shift of blood occurs from the systemic circulation back to the pulmonary circulation, increasing the mean pulmonary pressure and decreasing the mean systemic pressure. As a result, the outputs of the two sides of the heart once again become equilibrated.

Conversely, a sudden shift of blood from the systemic circulation into the pulmonary circulation is illustrated by the dashed-dot curves, showing a decrease in mean systemic pressure to 6 mm Hg and a rise in mean pulmonary pressure to 14 mm Hg. The net result is diminution of right ventricular output by approximately 10 per cent and enhancement of left ventricular output by approximately 40 per cent. Here again there is almost 2 to 1 disparity between

the outputs of the two ventricles, thus resulting in a rapid shift of blood out of the lungs into the systemic circulation; this shift continues until the right ventricular output rises to equal the falling left ventricular output. In this manner, the outputs of the two ventricles once again become re-equilibrated, thus explaining the experimental findings of many different investigators that the two sides of the heart always automatically re-equilibrate with each other within a few heartbeats (11, 18, 129, 159).

EFFECT OF ACUTE LEFT HEART FAILURE ON CARDIAC OUTPUT, VENOUS RETURN, LEFT AND RIGHT ATRIAL PRESSURES, MEAN SYSTEMIC PRESSURE, AND MEAN PULMONARY PRESSURE. Figure 25 illustrates the sequence of events that occurs when the left ventricle suddenly fails. Point *A* is the normal equilibrium point for the right ventricle and point *A'* the normal equilibrium point for the left ventricle. These two are in equilibrium with each other. Then, suddenly, the left ventricular output curve falls to less than one-half normal as depicted by the lower solid curve. Instantaneously, this depressed left ventricular output curve equilibrates with the normal left ventricular venous return curve at point *B* which represents only 30 per cent of normal output. Now a 70 per cent disparity exists between the momentary right ventricular output and the momentary left ventricular output, this causing blood to shift into the lungs from the systemic circulation (138, 139). In a matter of a few heartbeats the new venous return curves become the dashed

FIG. 25. Effect of sudden reduction in pumping effectiveness of the left ventricle. This shows a shift of both venous return curves (as illustrated by the dashed curves) to the left until right ventricular output falls (point *C*) to equal the rising left ventricular output (point *C'*).

curves of the figure, with the systemic venous return curve being governed by a new mean systemic pressure of only 4 mm Hg and the pulmonary venous return curve being governed by a very high pulmonary pressure of +28 mm Hg. Blood continues to shift from the systemic circulation into the pulmonary circulation until the output of the left ventricle rises to equal the falling output of the right ventricle. These conditions are reached at equilibrium point *C* for the right ventricle and equilibrium point *C'* for the left ventricle. Since the mean pulmonary pressure has risen to 28 mm Hg, the pulmonary circulation has become engorged with blood, and the pulmonary capillary pressure will probably be above the critical value of about 25 mm Hg, above which pulmonary edema begins to appear (94).

This is only a partial analysis because within the next 30 sec or so sympathetic reflexes will elevate at least three of the curves, the right ventricular output curve, the systemic venous return curve, and the left ventricular output curve, thereby resulting in a further elevated equilibrium level of cardiac output but also further increase in atrial pressures.

EFFECT OF ACUTE RIGHT HEART FAILURE. Figure 26 illustrates the sequence of events when the right heart fails acutely. Points *A* and *A'* represent normal conditions, and point *B* represents the instantaneous effect of the acute failure on right heart output, showing that the right heart output is only about one-half the output of the left ventricle at that point. Immedi-

ately, blood begins to shift from the pulmonary circulation into the systemic circulation (138, 139), and this shift continues until the left ventricular output falls to equal the rising right ventricular output. The new equilibrium points are *C* for the right heart and *C'* for the left heart, both of which now have the same ventricular outputs and venous returns of 700 ml per min. During the re-equilibration of blood between the systemic and pulmonary circulation, the mean systemic pressure has risen from 7 to 7.4 mm Hg, while the mean pulmonary pressure has fallen from 7.0 to 4 mm Hg. This minute increase in mean systemic pressure explains the failure of systemic vascular pressures to rise greatly in acute right heart failure (122, 181). After another moment or so, sympathetic reflexes tend to elevate the different curves as explained above, and the cardiac output can return part way toward normal.

EFFECT OF BLOOD VOLUME CHANGE. Figure 27 analyzes the effect of hemorrhage on the outputs of both ventricles. Note that the primary effect of reduced blood volume is to shift the scales for left and right atrial pressures, moving the zero pressure points toward each other. An increase in blood volume causes exactly the opposite effect. Here again, since the capacitance of the pulmonary circulation is only one-seventh that of the systemic circulation, the left atrial pressure scale is still one-seventh that of the right atrial pressure scale. Thus, in figure 27, the mean systemic pressure has fallen to 1.7 mm Hg and the

FIG. 26. Analysis of the effect of sudden right ventricular weakness on cardiovascular dynamics showing a decrease in right ventricular output to point *C* and left ventricular output to point *C'*.

FIG. 27. Effect of reduced blood volume on cardiovascular dynamics. This figure shows that the mean systemic pressure and mean pulmonary pressure are both greatly reduced, thus causing corresponding decreases in the two venous return curves.

mean pulmonary pressure to 2.5 mm Hg. Thus, the net effect of a decrease in blood volume is simply to reduce both the mean systemic and mean pulmonary pressures. This does not affect, at least temporarily, the output curves of either the left or the right ventricles until sympathetic reflexes occur. Also, it does not affect, at least temporarily, the slopes of the two venous return curves. Therefore, the only significant effect is a reduction in both the systemic and pulmonary venous return curves because of the reduced mean systemic and mean pulmonary pressures. As a consequence, both the right ventricular and left ventricular outputs are reduced, in this instance to approximately 55 per cent of normal.

SUMMARY OF THE COMPLEX ANALYSIS. This more complex analysis of the circulation has been presented to illustrate a method for analyzing the effects of unilateral excess load or unilateral alteration in pumping effectiveness of the heart. It has particular importance in analyzing abnormalities of the pulmonary circulation. On the other hand, as one can readily see from the last few figures, even when relatively large quantities of blood shift into or out of the pulmonary circulation, rather small changes occur in the dynamics of the systemic circulation. Therefore,

from a practical point of view, when one is concerned principally with systemic effects of the circulation, the simplified analysis is usually quite adequate.

Obviously, only a few examples of the vast number of uses of these two types of analysis have been given. Because of the multitude of different quantitative values that can be assumed by different venous return and different output curves, the analyses can likewise assume literally thousands of different forms. However, the various alterations in the individual curves that can occur under many different circulatory conditions obey rather simple principles. Therefore, in almost any circulatory condition, one can either establish the different curves experimentally or can predict them very accurately, and from these he can proceed with an analysis of the different effects which will occur in the circulation, particularly as they relate to venous return, cardiac output, left and right atrial pressures, pulmonary blood volume, and systemic blood volume.

SPECIFIC FACTORS THAT AFFECT VENOUS RETURN

Thus far, we have considered only a general analysis of venous return. Now we need to consider several factors that at times play highly significant and specific roles in the local process of blood flow along the veins. These include especially the effects of *a*) the venous pump, *b*) the collapse factor, *c*) central pressure pulsations, and *d*) local factors in the tissues that help to govern venous return such as local tissue activity and tissue utilization of oxygen.

EFFECT OF THE VENOUS PUMP ON VENOUS RETURN. Almost every student of physiology is already familiar with the function of the so-called "venous pump." That is, all peripheral veins beyond the visceral cavities are supplied with valves oriented toward the heart, and any factor that causes successive compressions of the veins exerts a pumping action that propels blood toward the heart. The different types of compression that have been implicated in the venous pump include *a*) compression incident to muscular movement either as a result of direct muscular pressure on the veins or indirectly as a result of movements of the joints and tissues, and *b*) pulsatile compression of the veins caused by arteries lying in the same sheaths as the veins. The second of these has not proved to be of any particular significance. Therefore, the venous pump is also frequently called simply the "muscle pump" (16, 17, 27, 49, 155, 156, 191).

In quiet standing, blood from the legs returns to the heart only with great difficulty, and the pressures in the veins of the lower limb rise to values equal to the weight of blood between the lower limbs and the heart, that is, to as much as 90 mm Hg. However, during walking, the venous return from the lower limbs will be so satisfactory that venous pressures in the feet may be as low as 20 to 25 mm Hg (156). In the absence of an active venous pump, a person can develop such high pressures in the lower part of the body when he stands that he actually loses as much as 15 to 20 per cent of his blood volume in less than one-half hour, thereby in many instances provoking fainting.

EFFECT OF VENOUS COLLAPSE ON VENOUS RETURN. The phenomenon of "venous collapse" is based on the simple fact that it is impossible to suck fluid through a collapsible tube. Since the heart is located in the thoracic cavity where the pressure is normally approximately -5 mm Hg and since the right atrial pressure often is also in the range of -2 to -3 mm Hg, suction frequently is applied to the central veins. This is particularly true of the veins entering from above downward when a person is in an upright position, because, under these conditions, the negative hydrostatic pressure of the blood flowing downward toward the heart adds to the negative pressures al-

ready in the chest, thus causing essentially complete collapse of the veins in the neck. However, this, too, is a very old story known by almost every student of physiology (34, 54-58, 112, 114, 170), and it can be summarized by simply saying that any factor which makes the right atrial pressure more negative than normal does not cause a significant increase in venous return. That is, the venous return will be as great when the right atrial pressure is approximately -2 mm Hg as it will be should the right atrial pressure fall to as low as -15 mm Hg. For instance, when a person breathes air from a chamber that is under negative pressure, this negative pressure is transmitted through his lungs to the chambers of his heart. Yet, breathing against the negative pressure does not increase the venous return to values above normal—all because the veins collapse any time there is an attempt to suck blood from the periphery.

Venous collapse also occurs whenever pressure is applied to the outside of the veins. This very frequently occurs in the case of elevated abdominal pressure (24, 88). Figure 28 illustrates the effect of intra-abdominal pressure on the pressure along the inside of the inferior vena cava. In these studies, a catheter was introduced upward from the femoral vein until it entered the right atrium, showing that the venous pressure all along the extent of the intra-abdominal veins was always slightly greater than

FIG. 28. Effect of increased abdominal pressure (*AP*) on pressures measured from the tip of a catheter inserted up the femoral vein and along the vena cava until it entered the right atrium. [From Guyton & Adkins (88).]

the intra-abdominal pressure. In other words, for blood to flow through a vein as it returns toward the heart, the pressure inside the vein must be greater than the pressure applied to the outside of the vein. If the abdominal pressure is 25 mm Hg, then the pressure in all the lower veins of the body that feed blood through the abdominal cavity, including the leg veins, must be greater than the 25 mm Hg intra-abdominal pressure. Likewise, if a bone or some other structure presses against a vein with a pressure of 10 mm Hg, the pressure in the vein beyond that point must rise above 10 mm Hg to force blood past the compression point. These are simple hydrodynamic principles.

EFFECT OF CENTRAL PULSATION ON VENOUS RETURN.

Probably the most extensively studied factor that has been considered to affect local venous flow is central pulsation. There are two different types of central pulsation which can affect blood flow to the heart. These are 1) increases and decreases in venous pressure resulting from the contractions of the heart itself (6, 21, 30, 124, 185), and 2) increases and decreases in central venous pressure resulting from respiration (1, 28, 32, 33, 62, 130, 149, 187). All studies that have ever been reported on phasic blood flow from the peripheral veins to the heart have demonstrated that the flow of blood toward the heart increases greatly during the negative phases of the central pressure pulses. Then, during the positive phases, blood flow becomes markedly reduced and can even flow backward from the right atrium into the veins. A very significant inflow of blood into the right atrium occurs during inspiration for two different reasons: First, movement of the diaphragm downward decreases the intrathoracic and right atrial pressures slightly, which helps to move blood toward the heart. Second, and much more important, downward depression of the diaphragm compresses the veins of the abdomen, thus forcing large quantities of blood toward the heart. Brecher and his colleagues (31) have recently been foremost among a long line of investigators, extending back a hundred years, in pointing out the phasic flow of blood to the heart caused by central pressure pulsations.

Still more important to our present discussion, however, is not whether or not blood flows into the heart in greater amount during the negative phase than the positive phase but, instead, whether or not central pulsation on the average aids venous return. Different investigators in the past have gone so far as to state that central pulsations are among the most

important of all the factors tending to return blood to the heart, while others have gone so far as to state that, if anything, central pulsations are harmful to the venous return rather than beneficial. Brecher's monograph on venous return presents very admirably the first point of view (31). On the other hand, studies from our own laboratories during the past year have indicated that central pulsations on the average (though not during the negative phases of the pulsations) cause considerable diminution of venous return rather than enhancement (91). For this reason, it would be impossible for the author to present any arguments in favor of the importance of central pulsations in returning blood to the heart. Therefore, the reader is referred to Brecher's thorough monograph for this point of view.

The basis for our belief that central pulsations are harmful rather than helpful, on the average, to venous return is depicted in figure 29. This shows the typical venous return curve, and it shows by means of the horizontal sine waves the central pulsation excursions, varying in this instance between the values -6 and $+2$ mm Hg. The figure then shows by the vertical pulsations the effects of these pressure changes on venous return as would be predicted from the venous return curve. Note that venous return is considerably depressed during the positive phase of the pulsatile cycle. On the other hand, venous return is only slightly increased during the negative phase. Therefore, the average venous return is decreased approximately 10 per cent as a result of the central venous pulsation.

To test this premise experimentally a cannula was inserted in the wall of the right atrium, and varying quantities of blood were injected and removed from the right atrium at frequencies varying between 60

FIG. 29. Effect of central pulsations on venous return, illustrating a rectification phenomenon that causes depressed venous return when central pulsations occur.

and 160 cycles per min and in volume between 0 and 64 ml per cycle. In over 200 successive records not a single instance of increased venous return occurred. On the contrary, even the minutest increase in right atrial pulsation always reduced venous return, and very intensive pulsations actually reduced venous return (at any given mean right atrial pressure) to as low as 50 per cent of normal. Thus, there is a "rectification phenomenon" occurring in the venous return to the heart. That is, on the negative pressure cycle collapse of the veins prevents very much enhancement of venous return, while on the positive pressure cycle, no such event prevents the positive pressure from reducing venous return (29, 36, 37, 44, 113, 118, 141, 151). The net effect, based on both theoretical grounds and experimental grounds, and supported by studies from other laboratories as well as from our own (54), is that central pulsations are not of any value in promoting venous return.

EFFECT OF LOCAL TISSUE ACTIVITY ON VENOUS RETURN—EFFECT OF OXYGEN USAGE BY THE TISSUES. The best known condition in which local tissue activity affects venous return is muscular exercise, in which case the venous return may be increased several fold. Earlier it was pointed out that this is caused both by an increase in mean circulatory pressure and by vascular dilatation in the muscles. The problem still remains, however, to explain the cause of the vascular dilatation in the muscles which in turn leads to the greatly enhanced venous return. In recent years, much evidence has accumulated that oxygen usage by the tissues might well be the initiating factor that controls vascular dilatation (9, 41, 45, 51, 64, 65, 77, 79, 119, 125, 136, 190, 199). Some research workers have felt that relative oxygen lack in the tissues causes them to form a humoral substance which then causes vasodilatation (7, 8, 15, 153). Humoral substances that have been suspected are carbon dioxide, hydrogen ions, adenosine phosphate compounds, histamine, and lactic acid. Thus far, however, none of these substances has been isolated in sufficiently large quantities from the blood to prove that it is truly acting as a vasodilator substance.

Another concept is that the tissue cells compete for the available oxygen in the arterial blood with the vascular smooth muscle, perhaps with the smooth muscle of the metarterioles and precapillary sphincters (45). If the tissues utilize excess oxygen, then the blood vessels will be without adequate oxygen. As a result, these vessels might dilate simply because their smooth muscle walls cannot remain contracted

in the face of oxygen lack. This concept is supported by the following experiment: venous blood was removed from the right ventricle, and arterial blood was removed from the aorta of the same dog at the same time. These two bloods were then alternately passed through an isolated hind limb of a dog in which the input and outflow pressures were controlled and in which the blood temperature was very exactly controlled. The arterial blood always caused vasoconstriction, while the venous blood always caused vasodilatation (to 250% of the arterial value). Furthermore, the degree of vasodilatation depended almost proportionately on the degree of unsaturation of the blood entering the limb as shown in figure 30. The only difference between the two bloods was that one had passed through the lungs and the other had not. Therefore, if any vasodilator substance were in the venous blood, then it would have to have been removed by the lungs. Since the lungs are not known to have this ability to remove vasodilator substances of any type, and since controlled breathing of carbon dioxide illustrated that carbon dioxide had no significant local effect on peripheral vascular flow, we must presume that it is lack of oxygen that initiates the vasodilatation in the limb and not some intermediary vasodilator substance.

The reason for discussing this oxygen lack theory of peripheral vasodilatation so completely is that, in the final analysis, it may be oxygen usage by the tis-

FIG. 30. Effect of reducing arterial oxygen saturation on the blood flow through an isolated hind limb of the dog. [From Crawford *et al.* (45).]

sues that is the primary factor which normally regulates venous return and, therefore, also cardiac output. That is, the degree of local dilatation of peripheral vessels would increase with each increase in local tissue activity; consequently, the return of blood to the heart would be governed by tissue utilization of oxygen. On summing all the individual flows through all the individual tissues of the body we obtain a summated value which equals venous return, and, since this automatically equates with cardiac output, the summated flows of the individual tissues are also equal to the cardiac output. Therefore, if it is true that oxygen lack in all individual tissues does cause vasodilatation, then we find that in the final analysis the rate of local oxygen utilization could be the single most important controller of venous return and cardiac output. Indeed, this is supported by many isolated studies of the relationship between oxygen utilization or oxygen lack and circulatory blood flow, beginning with the study of Douglas & Haldane (51) in 1922 in which it was shown that oxygen lack increases the cardiac output to a considerable extent, and extending through studies by Gorlin and co-workers showing a greatly increased cardiac output in severe oxygen lack (77), and a more recent study by Huckabee (119) showing an increase in cardiac output of as much as twofold in animals poisoned with cyanide.

Besides the acute peripheral dilatation that results from oxygen lack, a very marked additional increase in tissue blood flow occurs over a period of several weeks if excessive oxygen usage or oxygen deficiency persists for this long period of time (130a). This, however, results from increased "vascularity" of the tissues, that is, increased numbers of blood vessels. Nevertheless, this too, despite its slowness to develop, represents a very important and very powerful regulatory mechanism for control of venous return in response to oxygen need by the tissues.

Aside from the experimental observations on the control of venous return and cardiac output by oxygen lack, there is one compelling theoretical reason for believing that oxygen lack should be the main controller of venous return and cardiac output, and that is the following: Of all the essential substances supplied to the tissues by the blood, oxygen is by far the one most critically dependent upon an adequate blood flow. For instance, blood flow can be decreased to as little as $1/20$ normal, and adequate quantities of glucose, fats, and proteins can still be carried to the tissues. Also, if the depth of breathing

is increased, carbon dioxide can be carried away from the tissues in adequate quantities even when the cardiac output is decreased to as little as $1/10$ normal. On the contrary, the tissues become severely damaged from anoxia whenever cardiac output remains only slightly below normal for a prolonged period of time. Therefore, it is readily obvious that oxygen transport to the tissues is normally markedly "flow limited," while the transport of no single other essential substance to or from the tissues is limited to a significant extent under normal or anywhere near normal conditions. For this reason, it is especially reasonable that oxygen should be the major regulator of venous return and cardiac output; this would provide a closed loop regulatory system that would help to maintain an adequate supply of oxygen to all the tissues at all times.

VENOUS PRESSURES

The regulation of venous pressure is inextricably related to the regulation of venous return and cardiac output, as has already been pointed out in both the simplified and more complex circuit analyses presented earlier in this chapter. All the different significant factors which affect right atrial pressure have already been discussed. On the other hand, the right atrial pressure is not the same as the more peripheral venous pressures. Therefore, we need now to conclude our discussion of the return of blood to the heart by summarizing the different factors that determine the peripheral venous pressures. These include, first and paramount, the right atrial pressure itself. In addition, they include *a*) resistance to blood flow along the veins, *b*) rate of blood flow in the veins, and *c*) hydrostatic pressure effects.

EFFECT OF RESISTANCE TO FLOW IN THE VEINS. Dilated central veins are so large that they have almost no resistance to blood flow, but semicollapsed veins, on the other hand, have very high resistance. This effect is particularly important at the different compression points where the veins pass over the ribs or lie against some relatively solid organ (52, 53). In the ordinary circulation, therefore, the resistance to venous flow is not negligible, principally because of the compression points against the veins. On the other hand, when the right atrial pressure rises to a very high value, blood can dam up in the veins, elevating the pressures in the veins to values equal

to or perhaps considerably greater than those on the outside of the veins. In these instances the vein become distended and the venous resistance becomes automatically reduced. This turns out to be an important safety factor in venous return, for often an elevated right atrial pressure results from a damaged heart, in which case return of blood to the heart would become inadequate if the venous resistance should remain as high under these conditions as it is in the normal circulation. Fortunately, however, the reduced resistance of the veins allows the existing pressure gradient from the periphery to the heart to force blood toward the heart almost equally as well as it occurs normally. For this reason, the peripheral pressures ordinarily do not rise significantly until the right atrial pressure has risen above approximately +4 to +6 mm Hg (74). Above this point, the veins by then will have become distended, and any additional rise in right atrial pressure is there- after reflected by a similar increase in peripheral venous pressure (83).

EFFECT OF VENOUS FLOW ON PERIPHERAL VENOUS PRESSURES. An increase in the volume of venous blood flowing toward the heart theoretically would cause essentially the same effects on peripheral venous pressures as would an increase in venous resistance. However, from a practical point of view this is not true, because an increase in volume of flow normally simply distends the collapsed veins to a greater degree, thus reducing the resistance to flow. The flow and decreased resistance ordinarily compensate for each other so that increasing the flow has relatively minor effect in increasing the peripheral venous pressures rather than a major effect as might be expected (88). This has been demonstrated especially in the case of blood flowing from the peripheral limbs through the abdominal cavity when the intra-abdominal pressure is elevated. For instance, if the intra-abdominal pressure is +10 mm Hg, whether the flow from the leg to the right heart is 0.5 ml per min or 200 ml per min, the pressure in the femoral vein leading into the abdominal cavity still remains only 1 mm Hg or so greater than the 10 mm Hg intra-abdominal pressure.

EFFECT OF HYDROSTATIC PRESSURE ON PERIPHERAL VENOUS PRESSURES. Finally, we have the well-known effect of hydrostatic forces on peripheral venous pressures. That is, the simple weight of the blood increases the venous pressures in the dependent

parts of the body and creates negative pressure in areas above the heart. The collapse factor and the venous pump that modify these pressures were described earlier in the chapter. Particularly important is the fact that the veins of the neck collapse and their resistances automatically become greatly elevated. Therefore, venous pressure in the neck almost never falls below atmospheric pressure unless unusual circumstances prevent the veins from collapsing.

Because of the importance of the hydrostatic factor in all venous pressure measurements, two very similar methods have been suggested for determining a "physiological zero" pressure in the venous system (93, 111). The second of these, which was presented from our laboratory, depends on rotating a dog about two different axes. It was found that venous pressures referred to a point barely inside the right ventricle at the tricuspid valve did not vary a measurable amount regardless of the position of the animal.

SUMMARY

To summarize this entire chapter, its important point has been that one cannot analyze venous return separately from a simultaneous analysis of many other factors in the circulation. However, relatively simplified analyses, based principally on four major segments of the circulation, the right heart, the pulmonary circulation, the left heart, and the systemic circulation, can provide an almost complete understanding of the interrelationships between *a*) venous return, *b*) cardiac output, *c*) right atrial pressure, *d*) left atrial pressure, *e*) mean systemic pressure, *f*) mean pulmonary pressure, *g*) mean pulmonary volume, and *h*) mean systemic blood volume.

If we should choose any single factor that might be the primary regulator of venous return, and hence also the primary regulator of cardiac output, it might be the tissue utilization of oxygen. Certainly, in over half of the tissues of the body if not in the entire body, local blood flow seems to be controlled by the local utilization of oxygen, and the summated value of all the local flows is the venous return. Therefore, oxygen utilization by the tissues might well be, in the final analysis, the primary regulator of venous return.

Summary

INTRODUCTION

General Physical Chemistry of Ions

We are here concerned only with pointing out in simplified form the basic physical-chemical features of ions and the manner in which these affect their role in biological processes. For detailed treatment of this subject the reader is referred to standard chemistry texts as well as to the basic articles of Conway (31, 32), Hodgkin (112) and Shanes (182, 183).

OSMOTIC EQUILIBRIUM. We may begin by considering osmotic pressure to be the equivalent of the mechanical pressure which must be applied to a solution to prevent osmosis of the surrounding solvent into the solution through the membrane. It is, therefore, not

¹ Submitted for publication December 20, 1960.

primarily a characteristic of the membrane but is a measure of some real difference between pure solvent and solution. The membrane merely allows this difference to show itself.

The osmotic pressure, Π , of any solution is proportional to temperature and concentration:

$$\Pi = kCT$$

Accordingly, in dealing with a cell, we must consider the osmotic pressure not only of the solution inside the cell but also that of the environment which bathes it. The cell contains an amount of nondiffusible material in solution which is essential to its metabolism. Clearly, the amount of this material which can be retained without causing the cell to swell will be sharply limited unless there is also a counterbalancing nondiffusible material outside its membrane. This is perhaps the major niche into

which evolution has fitted the sodium ion. Cell membranes are almost impermeable to this ion and, since the cellular nondiffusible material is almost constant, the amount of cellular water is controlled by variations in extracellular sodium, Na_o . Conway (31) has demonstrated this point by showing, for example, that K concentration in the medium, K_o , can be varied over wide limits without influencing the basic dependence of cell volume on Na_o after equilibration (fig. 1). This essential point is often overlooked in experiments dealing with alterations of the medium.

The development of osmotic pressure is one of the colligative properties of solutions. Ideally it is determined by the number of particles in solution:

$$\Pi V = nRT$$

Its expression, however, depends on whether or not the membrane is permeable to the particle in question. At equilibrium, no osmotic pressure is exerted by a particle to which a membrane is freely permeable.

FIG. 1. The dependence of sartorius weight on $[\text{Na}^+]$ of the medium (24-hour immersion at 3 C). Closed circles: stepwise NaCl reduction replaced by KCl. Crosses: stepwise NaCl reduction not replaced by KCl. Open circles: stepwise NaCl reduction in the presence of cyanide (2×10^{-3} M). Volume control at equilibrium depends on $[\text{Na}^+]$ even in the presence of cyanide and is independent of $[\text{K}^+]$ above maintenance level (20 meq/liter). [From Conway (31).]

ION SIZE. Ions may be defined as particles which have gained or lost an electron on passing into solution. The elements of Group 1 of the periodic table, the alkali metals Li, Na, K, Rb, and Cs, are all characterized by possessing a single electron in their outer orbital shell. In solution this is lost so that the element loses its electroneutrality and remains positively charged as Li^+ , Na^+ , etc. Other elements, like those in Group 7, take up one or more electrons into their outer shell and so become, in solution, negatively weighted, e.g., Cl^- , Br^- , I^- , etc. The formation of ions is not restricted to elements but also occurs with more complex radicals which can collectively gain or lose one or more electrons, e.g., OH^- , NH_4^+ , etc.

Ions share the ordinary colligative properties of substances in solution as, for example, freezing point depression, osmotic pressure, etc. Additionally, they possess a number of special properties based on the fact that they are electrically charged.

We must distinguish here the size of the ion considered as a solid ball, so to speak, and defined by its crystal radius, from its size when associated with water molecules and defined by its hydrated radius. The increase in size of the monoatomic crystals of Group 1 falls naturally into the same order as their periodic arrangement $\text{Li} < \text{Na} < \text{K} < \text{Rb} < \text{Cs}$.

For many years it has been the accepted practice to emphasize the hydrated ion in biological systems.

TABLE 1. *Ionic Radii of Alkali Metal Ions*

| | Crystal Radius, Å | Hydrated Radii, Å From Mobility |
|------------------------------|-------------------|------------------------------------|
| Li | 0.60 | 2.31 |
| Na | 0.95 | 1.78 |
| K | 1.33 | 1.22 |
| Rb | 1.48 | 1.18 |
| Cs | 1.69 | 1.16 |
| NH ₄ ⁺ | 1.48 | 1.21 |

From Ussing *et al.* (202).

The smaller the ionic crystal the more densely is its electrical field packed and the greater its attraction for water dipoles. Consequently, the size of the package, crystal plus water, moving in a solution, is larger the smaller the crystal. Thus, the rank order for the hydrated ion size is Cs < Rb < K < Na < Li (table 1). This model should not be accepted uncritically (160) although it does provide us with a useful working framework.

ION ACTIVITY. Ions in solution are subject to interionic forces which limit their availability. In consequence, the measured concentration of an ion may be greater or less than its reactive concentration by some measurable degree defined as the activity coefficient. The concentration of the substance, corrected by the activity coefficient, defines the activity of the ion in the given solution. Since reactions in solutions and their resultant equilibria are determined by activities rather than by concentrations this point has special importance. As figure 2 shows, each salt has its own characteristic curve relating activity to concentration. Standard tables are available. For similar reasons, the ionization constant of salts is also of import, since not all salts dissociate with equal completeness into ions. Activity will be symbolically written (Na⁺) and concentration [Na⁺]. Where such precision is not necessary in a given context we shall simply write Na for sodium or Na⁺ for sodium ion.

ION MOBILITY. In general, the mobility of an ion in free solution varies inversely with its hydrated size. In fact, the concept of ion hydration was in part developed to explain the relative mobilities of ions. Ion mobility is ordinarily measured as velocity in a standard electrical field. Table 2 shows the relation of increasing size to slower velocity.

ION PENETRABILITY OR MEMBRANE PERMEABILITY. Cell membranes in general appear to have channels so limited in size as to allow K to enter freely and just

FIG. 2. Mean activity coefficients of various electrolytes at 25 C. [From Prutton & Maron (161a).]

to exclude Na. Conway (32) has presented interesting and basic data pertinent to this point (table 3). Frog sartorius immersed in Ringer fluid, to which 100 mm of a particular salt is added, at first loses weight (osmotic withdrawal of water). Then, if the membrane is freely permeable to the salt, the weight increases back to its original base. Thus, at equilibrium, the added salt has not upset the osmotic balance. The time required to recover 50 per cent of the weight loss is taken as a measure of the permeability of the membrane for the particular ion and table 3 is so constructed. It is evident that taking KCl as standard, RbCl and CsCl enter readily, while the chlorides of Na, Li, Ca, and Mg do not enter appreciably. Similarly, in the anion series, bromide and nitrate enter easily while phosphate, acetate, bicarbonate, and sulfate are excluded.

On the right side of the table Conway compares the diffusion coefficients of the ions rather than relative ion diameter with K and points out that the correspondence is far from exact (cf Rb and Cs penetration rates with diffusion rates).

The permeability of the cell membrane to ions is not a fixed characteristic but must be expected to vary physiologically and pathologically.

TABLE 2. *Relation of Ion Size to Mobility in an Electric Field*

Velocities of Ions Under Gradient of 1 V/cm or 0.5 V/cm for Divalent Ions

| Cations | | Anions | |
|-----------------|-------|---------------------|-------|
| H | 315.2 | OH | 173.8 |
| Rb | 67.5 | Br | 67.3 |
| Cs | 64.2 | I | 66.2 |
| NH ₄ | 64.3 | Cl | 65.2 |
| K | 64.2 | NO ₃ | 61.6 |
| Na | 43.2 | CH ₃ COO | 35.0 |
| Li | 33.0 | SO ₄ | 34.0 |
| Ca | 25.5 | HPO ₄ | 28.0 |
| Mg | 22.5 | | |

From Conway (32).

TABLE 3. *Relative Entrance Rates of Ions into Muscle (Left Column) Compared with Their Diffusion Constants, D, Through Water Relative to K Taken as 100 (Right Column).*

| Cation series | | D for single ions, with K value = 100 | |
|--------------------------------|-----|---------------------------------------|-----|
| KCl | 100 | K | 100 |
| RbCl | 38 | Rb | 103 |
| CsCl | 8 | Cs | 104 |
| NaCl | 0 | Na | 67 |
| LiCl | 0 | Li | 52 |
| CaCl ₂ | 0 | Ca | 40 |
| MgCl ₂ | 0 | Mg | 35 |
| Anion series | | | |
| KCl | 100 | Cl | 100 |

| K phosphate | 4 | H ₂ PO ₄ | 50 |
| KOOC·CH ₃ | 3 | HPO ₄ | 39 |
| KHCO ₃ | 1 | CH ₃ COO | 54 |
| K ₂ SO ₄ | 0 | HCO ₃ | 67 |
| | | SO ₄ | 53 |

From Conway (31).

Special Properties of Ions in Biological Systems

DONNAN EQUILIBRIUM. By thermodynamic principles it can be demonstrated that the product of diffusible cations and anions on the two sides of a membrane must attain equality at equilibrium. Thus:

$$(\text{cations})_i(\text{anions})_i = (\text{cations})_o(\text{anions})_o$$

When the cell is nonpermeable to some charged material on one side of its membrane, a sufficient number of diffusible ions of opposite charge is required to balance this. In the cell this fixed material is mainly negative in charge so that it can be shown that at equilibrium the sum of the diffusible cellular cations must be rather larger than the sum of diffusible anions. In brief, this shows up in the low

Relative Ion Diameters (Diameter of Potassium Ion = 1.00)

| Cations | | Anions | |
|-----------------|------|---------------------|------|
| H | 0.20 | OH | 0.37 |
| Rb | 0.96 | Br | 0.96 |
| Cs | 1.00 | I | 0.97 |

intracellular and high extracellular Cl⁻. It is important to realize that in determining an expected Donnan equilibrium in a tissue only the diffusible ions count. Thus, Na⁺ figures only to the small extent that it penetrates the cell membrane.

ELECTROCHEMICAL GRADIENTS AND MEMBRANE POTENTIALS. It is beyond the scope of this article to attempt to deal with this fascinating subject in any sort of detail. Since our discussion of ions and smooth muscle must make frequent reference to bioelectric potentials, however, a brief outline will be presented.

Two different dilutions of a substance A' and A'' have necessarily different activities and different chemical potentials stored in them. This may be expressed as the change in free energy required to move one mole of A' from the lower to the higher activity or, conversely, the amount of free energy liberated when A'' slides from higher to lower activity. This relation follows the very general form

$$\Delta G = RT \ln \frac{(A)'}{(A)''}$$

ΔG can be expressed in electrical terms as volt-coulombs and factored into a potential difference E and nF faradays so that:

$$E = \frac{RT}{nF} \ln \frac{(A)'}{(A)''}$$

At 25 C this simplifies to

$$E_{(mv)} = 58 \log \frac{(A)'}{(A)''}$$

Clearly, the osmotic balancing of the nondiffusible material in the cell and the associated Donnan rearrangement together produce a situation in which the diffusible ions are distributed unequally on the two sides of the membrane and so contain stored energy.

By far the major diffusible ion concerned is K^+ and so we may write as a first approximation:

$$E_m = \frac{RT}{F} \ln \frac{(K^+)_i}{(K^+)_o}$$

where E_m is the potential at equilibrium across the membrane and i , inside, o , outside. Concentrations are usually written but activities, as shown, are more precise.

The movements of Na^+ and Cl^- are essentially quite limited; yet, to the extent that they are permeable, their distribution must also contribute to the over-all transmembrane potential. Goldman (92) has therefore proposed a constant field equation:

$$E_m = \frac{RT}{F} \ln \frac{(K^+)_i + p(Na^+)_i + p(Cl^-)_o}{(K^+)_o + p(Na^+)_o + p(Cl^-)_i}$$

By convention E_m is regarded as positive. The symbol, p , expresses the permeability of the ion relative to K^+ taken as unity, influx and efflux being considered separately. This equation may or may not be entirely correct but it is applicable to our purpose, since it takes into account the contributions of ions other than K^+ and their relative mobilities.

Special Properties of the Physiologically Important Ions

The particular role of Na^+ and K^+ has already been described. They are the major bulk ions of the body and, in fact, the maintenance of their distribution may consume a major share of the body's energy. Their role has been the subject of comprehensive monographs (61, 202).

Calcium and magnesium, belonging to Group 2 of the periodic table, have in their outer orbital shell two electrons which are given up readily in solution. They may, and probably do, participate in the phenomena described above, but they are also particularly important in enzymatic processes. They are far more readily complexed than either sodium or potassium.

Hydrogen and hydroxyl ions are distinguished by their mobility and easy penetrability into and out of cells. Their primary involvement in acid-base equilibria needs no comment at this point.

The physiologically important anions have also been the subject of an extensive monograph (54).

CLASSIFICATION AND CRITICAL APPRAISAL OF METHODS

It is not our purpose here to describe all the methods used to study the effects of ions on vascular smooth muscle directly or indirectly. The aim is rather to seek the general principles underlying each approach and to indicate to what extent the methods used can further our understanding. On this basis we can classify the methods broadly into two groups: those in which the experimental variable is the cell environment and those in which the vascular tension is the manipulated variable.

Studies of Vascular Smooth Muscle Tension Associated with Manipulation of the Milieu

In these studies the ionic milieu or environment of the cells has been manipulated *in vivo* by varying the dietary salt intake or by loading with various salts given by stomach tube, by infusion, or by injection. In this group we have, too, studies of the effects of hormones known to affect salt metabolism and *in vitro* studies in which the medium has been directly manipulated. Obviously, the more prolonged the treatment and the more general its effects, the more difficult it is to pin down any direct relation between treatment and vascular smooth muscle tension. Even so, all approaches must be examined if we are not to lose sight of important clues.

The effects of these manipulations, of varying degrees of remoteness from the target, have been assessed by three principal methods.

MEASUREMENT OF DIASTOLIC BLOOD PRESSURE. Since a major determinant of the diastolic blood pressure is the peripheral vascular resistance this approach has some limited value. The results can always be attacked on the grounds that a change may indicate an effect on cardiac output, on blood viscosity, or on blood volume, etc., rather than on peripheral resistance. Such studies have value, however, if they correlate well with other more direct approaches. Experiments of this type in the rat suffer still more seriously from the fact that most of the indirect methods do not measure diastolic blood pressure at all but some mixed level which approximates the mean pressure.

MEASUREMENT OF PERIPHERAL RESISTANCE IN REGIONAL VASCULAR BEDS. This approach is necessarily confined to studies of the effects of fairly rapid changes in the milieu. Within this limitation, it can be highly

accurate. The variable of cardiac output can be eliminated by controlling the rate of inflow into the vascular bed with a constant output pump (101). It can remain as a variable when blood flow rate and pressure are monitored simultaneously in the vascular bed under study (148). Additionally, this type of approach can give direct information concerning vascular tonus in different segments of a given bed. At the present time, in vivo studies carried out in this manner are the best available.

The alterations of the environment attainable with this approach are exceedingly limited if the circulation of the bed is continuous with that of the general systemic pool. The imposed change must not be great enough to elicit a systemic reaction and the change of milieu induced must be analytically confirmed. To avoid these difficulties many studies have been carried out using totally isolated vascular beds, e.g., rabbit ear, dog hind limb, rat hind limb, perfused with artificial solutions. The gain in control of the medium does not, however, compensate for the loss of a physiological preparation; hence such studies have not been extensively used for our particular problem.

Microscopic observations of various circulatory beds have yielded useful information concerning the physiology and pharmacology of these beds (114). Because the mesoappendix or meso-omentum, the beds usually studied (217), have rather special properties, they have not been extensively or profitably used to study the effects of ions.

MEASUREMENT OF TENSION IN THE VASCULAR STRIP OR RING OR IN AN ANALOGOUS SMOOTH MUSCLE STRIP. The in vitro approach has the value of enabling the experimenter to control the environment although, of course, the results must later be fitted to the in vivo framework. This type of study has suffered greatly from the fact that, so far, no one has been able to mount a representative of the vessels that actually control peripheral resistance. As substitutes, rings of large arteries or strips of aorta (87) have been used, although Bohr & Goulet (14) have recently reported briefly that a spiral strip of rabbit mesoappendix arteriole may be practicable.

The aorta seems to us a particularly poor choice because of its specialized elastic tissue content. It behaves quite differently from peripheral vasculature in vivo and, in particular, shows a slow and prolonged response time (11, 48, 88). An additional criticism is that the smooth muscle cells are abnormally oriented in the spiral strip. One would hope that a suitable preparation using a length of artery under intra-

luminal pressure distributed radially from its fluid content will soon be devised to replace the present strip techniques. Paton (157) and Davey (44) have both had some success with this approach and our own preliminary studies seem promising. For the present, we must discuss the results derived from current techniques with necessary reservation.

Although it is clear that different types of smooth muscle differ in their drug responses, they do have certain histological features in common. We shall, therefore, round out this part of the discussion by surveying the findings with uterus and gut strips in order to recognize generalizations where possible.

Studies of the Milieu During Manipulation of Vascular or Analogous Smooth Muscle Tension

In these studies, vascular smooth muscle tension has been increased or decreased, acutely or chronically, by a diversity of procedures ranging from hormones through drugs to direct ionic manipulation. Some well-defined parameter outside and/or inside the cell has been measured. The principal analyses are as follows:

MEASUREMENT OF EXTRACELLULAR AND OR INTRACELLULAR IONS AND WATER. The external environment of the smooth muscle cell has for a long time been estimated from measurements chiefly of plasma Na, K, Cl, and Ca. The analytical procedures have gradually been improved but Na determination by flame photometry with greater than 1 per cent error, exclusive of the sampling error, has made the world of small changes in plasma or serum Na unapproachable.

More recently it has become apparent that a knowledge of the extracellular fluid volume is required if extracellular ionic quantities are to have any meaning. The volume distribution of exogenously administered inulin so far gives the most reliable estimate of this (89, 206, 207). Earlier studies used chloride which, under basal conditions, was thought to be almost entirely extracellular. It is now generally realized, however, that not only is the chloride space larger than the extracellular space but also that procedures which alter cation distribution of necessity produce variable chloride shifts for the preservation of electroneutrality within the cell. Accordingly, we must interpret the ion partitions based on chloride measurements with caution. Other substances such as bromide or thiosulfate used as measures of extracellular space suffer from similar criticisms.

TABLE 4. *Some Representative Vascular Tissue Analyses*

| Author | Tissue | Total Na, meq/kg Dry Wt. | Total K, meq/kg Dry Wt. | Total Cl, meq/kg Dry Wt. | Total H ₂ O, ml/kg Wet Wt. | Cell Na, meq/l. | Cell K, meq/l. | Cell H ₂ O, ml/kg Wet Wt. | Inulin Space, ml/kg Wet Wt. | Cl Space, ml/kg Wet Wt. | Na Space, ml/kg Wet Wt. |

Sample analyses of nonvascular smooth muscle are presented for illustration. Estimate of variance is omitted wherever original data were recalculated to fit the tabular description. Derived data depend on either inulin or chloride space value shown on same horizontal line. (Table prepared by Dr. F. A. Sréter.)

Tissue analyses have also been carried out in an attempt to measure Na, K, and water and their extracellular/intracellular partition under a variety of conditions. Few of these have encompassed a representative vascular tissue, and even these few have been quite incomplete. Table 4 presents basic data taken from the work of several laboratories.

Total aorta Na and K vary from about 200 to 350 and 95 to 150 meq per kg dry tissue, respectively, the variation probably reflecting the animal's age, previous diet, and the sampling method. An aorta sodium so much higher than potassium is consistent with a large extracellular space.

It is apparent that the chloride space sometimes exceeds the readily measured total water content of the tissues and hence is a poor measure of extracellular space. Tobian & Binion (196), for example, reported an extracellular fluid volume based on chloride which recalculates to some 750 ml per kg wet tissue and this exceeds most investigators' estimates of total water. Dodd & Daniel (49) reported a chloride space of 633 and a sodium space of 650 ml per kg rabbit aorta, and again the total tissue water was only 640 to 660 ml

per kg. They argued that there was probably a fraction of bound chloride wrongly included in the calculation. Even after a correction for this, however, they still obtained an extracellular fluid volume of 483 ml per kg.

Using inulin in a revised procedure we estimate extracellular space as about 50 per cent of the total tissue water. This compares favorably with the estimate of Prosser *et al.* (161) of 39 per cent of the total tissue volume.

The ratio of extracellular to total water runs lower in other types of smooth muscle than in aorta. Inulin space measures 12 per cent of the total water in cat small intestine (9) and 34 per cent in the rabbit uterus (39). These again are in line with the electron microscopic observations. [The high inulin space reported for the immature cat uterus (39) is out of line.]

Intracellular Na runs higher in the aorta and in other types of smooth muscle than in skeletal muscle.

MEASUREMENT OF OSMOTIC PRESSURE AND PH. The development of techniques suitable for measurement of osmotic pressure and pH in small samples has made

it quite feasible to study these parameters directly. Unfortunately, these have not been much applied to the problem of ions and vascular tissue. This is an important deficiency.

ELECTRICAL MEASUREMENTS. It is now generally believed that electrical potentials developed across cell membranes depend on ionic distribution, mobility, and the permeability characteristics of the membrane itself. Unfortunately, because of technical difficulties, vascular tissue has not been approached until very recently and only minimal information is available. We shall thus have to lean heavily on electrical measurements obtained from other types of smooth muscle, especially guinea pig taenia coli.

CONTINUOUS MONITORING OF Na OR K ION ACTIVITY. The development of ion-specific glasses responding especially to Na^+ or K^+ (55) has made it possible to prepare electrodes suitable for monitoring Na^+ or K^+ in flowing blood (79). These electrodes can discriminate ion activity with far greater resolution than any methods hitherto available and can also be applied to the analysis of single samples or to the continuous monitoring of activity in a tissue bath. Their application to the problem in hand has only just begun, but already they have furnished several important pieces of information.

ROLE OF SODIUM AND POTASSIUM IN VASCULAR SMOOTH MUSCLE TENSION

Evidence from Studies of Diastolic Blood Pressure or Reactivity

GENERAL RELATION OF Na AND K TO CLINICAL AND EXPERIMENTAL HYPERTENSION. More than 50 years ago Ambard & Beaujard (4) suggested that the development of clinical hypertension was abetted by salt, although they incorrectly stressed Cl^- rather than Na^+ . Allen & Sherrill (2) revived the idea some 25 years later, correctly identified Na^+ as the important ion, and urged the use of low salt diets in treatment. After a period of neglect the idea recurred when Kempner (126) advocated the unpalatable rice diet for hypertensive patients and indeed, in so doing, came close to starting a food cult (27). Shortly thereafter the main therapeutic benefit of the rice diet was distinguished from its psychological benefit and shown to reside in its low sodium content (34, 98, 159). By the beginning of the last decade the low sodium diet

was firmly established as a measure of limited but certain usefulness in the management of the hypertensive patient. Because of difficulties inherent in its use it could not be widely applied but, even so, patients were routinely encouraged to reduce their voluntary salt intake for fear of accelerating the progress of their disease.

The effort to reduce the amount of sodium available to the body in hypertension led naturally to attempts to increase its loss through the kidneys. This approach was dramatically successful as specific natriuretic agents, such as chlorothiazide and hydrochlorothiazide, were developed and shown to be highly effective in the treatment of hypertension (1, 8, 97). These agents show clearly that as long as the kidneys are competent, the simple desalting of the body will reduce an elevated diastolic blood pressure and, even though normotensive levels may not be attained, will tend to keep it down.

Studies of experimental forms of hypertension have also underlined the general relation between available salt and blood pressure. This was first shown by the fact that hypertension induced by the prolonged administration of desoxycorticosterone acetate (DCA) is accelerated by concomitantly increasing the salt intake (179). This effect was shown to be specifically due to the sodium ion (180). A slower blood pressure rise can be induced without adding extra salt to the intake above that supplied by the food, but no rise occurs if the diet is sodium-free (18, 84, 181). A similar dependence on Na intake has been found to obtain for the hypertension which occurs during adrenal regeneration (184, 185) and in the subtotaly nephrectomized animal (128). Thus far, most forms of experimental hypertension respond to Na deprivation or depletion with a reduction in blood pressure (194).

The implication of Na metabolism in the hypertensive process has also been sharply underlined by studies of the response of man and animals to acutely imposed salt loads. The results have been strikingly uniform and the accelerated excretion of such loads, first systematically demonstrated in various forms of hypertension in the rat (77, 93), is also a consistent feature in hypertensive man (35, 94).

There is reliable but not so extensive evidence implicating K in a general way with the hypertensive process. Most of these studies have come from M. Friedman and his associates. These investigators first pointed out that the rise in blood pressure produced by renal compression in the rat can be reduced by prolonged K deprivation (6 weeks) and argued that this effect is related to the decrease in smooth muscle

tonus known to occur in gut and urinary bladder during potassium deficiency (72, 170, 210). An adequate K intake was also shown to be essential for the development of DCA hypertension although, unlike the effect of Na, an excessively high K intake does not accelerate the process (68, 169). In later studies, these authors concluded that the effect of varying the K intake depends on its simultaneous relation to the Na intake and that the development of hypertension depends on a high K/Na ratio (167, 169). This important theme will recur in our later discussion. Perera (158) confirmed the basic observation by showing that essential hypertension in man could be reduced by a low K diet, although this was not a practicable therapy.

EFFECTS OF VARYING NA AND K INTAKE OR LOSS ON BLOOD PRESSURE. Sapirstein and associates first reported in 1950 (172) that rats given various hypertonic NaCl solutions to drink develop an arterial hypertension after a latency of 1 to 4 weeks. This was confirmed by Toussaint *et al.* (201) and extended by Meneely and his collaborators (151, 152) who showed that the rise in blood pressure in such salt fed animals is proportional to their salt intake. A latter report from this same laboratory (150) pointed out that the effect of adding NaCl to the diet can be partly offset by a simultaneous increase in K as well. From this, they suggested that the blood pressure rise is dependent on an increase in the Na/K ratio. This is diametrically opposite to the work of M. Friedman and co-workers, cited above, which implicated a high K/Na ratio.

Fregly (71) has sharply underlined the importance of salt as a determinant of vascular resistance. He has recently produced hypertension in the adrenalectomized salt-fed rat and has shown the relation of the blood pressure rise to the amount of salt ingested. Vick *et al.* (203) found that vascular sensitivity, measured as the response of the aorta strip to epinephrine, increased in rats after 10 to 15 weeks of high salt feeding.

The idea that an excessive intake of salt may itself be a sufficient etiological factor in essential hypertension has been staunchly supported. In an extensive series of studies Dahl and his colleagues (36-38) have attempted to relate the incidence of hypertension in man to his salt-eating habits. Others have studied areas of reputedly high or low salt intake in order to relate the incidence of hypertension to the dietary habits of the inhabitants (176, 194). So far, however, the evidence that Na intake plays a primary etiological role is still shaky.

A serious deficiency in Na may occur naturally during exposure to excessive heat; the advance of the deficiency is associated with vascular collapse (100). Excessive salt depletion for therapeutic purposes may produce a similar picture (175). In the rat, acute Na depletion may be readily induced by equilibrating an intraperitoneal isosmotic mannitol or sucrose solution with the extracellular compartment. Such a depletion is always accompanied by hypotension (unpublished observation).

Although the prolonged intake of large amounts of K does not affect the blood pressure of the normotensive rat, K restriction is an effective hypotensive procedure (66). The depressor effect depends on the associated Na intake, for it does not occur in the presence of a low, but only with a normal to high intake (67). Such K-deficient hypotensive rats show a marked decrease in pressor response to epinephrine, norepinephrine, angiotensin, and renin (168). Both basal blood pressure and reactivity are rapidly restored by KCl given subcutaneously (72).

These highlights selected from an extensive literature show the limitations of this type of approach. They also show, however, that sodium and potassium can be implicated in the regulation of blood pressure and that sodium in particular plays some kind of critical role in hypertension. Unfortunately, too many steps intervene in the processes to permit any kind of valid interpretation. Even as far as this type of information is concerned we are faced with a major omission, for there is no assessment of the possible role of water in relation to salt intake. Sapirstein (171), in an attempt to reconcile the conflicting evidence, has drawn attention to the importance of water in the renal handling of electrolytes. It is evident that animals given various salt solutions to drink are confronted in each case with a fixed ratio of salt to water, and an ensuing rise in blood pressure may reflect either the increased salt ingestion or the inability of the animal to make an adjustment in its water intake. Similarly, in states involving salt loss, any speculation must also take into account the simultaneous changes in water distribution. McCance & Morrison (143) have pointed out this unsatisfactory aspect of experiments which do not distinguish between salt and water as separate variables.

Evidence from Studies of Tension or Reactivity of Vascular or Analogous Tissue

EFFECTS OF MANIPULATION OF NA IN THE MEDIUM. There is consistent evidence that the exposure of

smooth muscle to a sudden reduction of Na concentration in the medium, Na_o , osmotic pressure being held constant, produces an immediate increase in tension (116). This increase in tension is not sustained as equilibration proceeds. Streeten & Vaughan Williams (189) noted an increase in motility of intestinal loops (dog) during the first stage of Na depletion by intraperitoneal lavage. Whitehead (208) noted an increase in tone of isolated ileal or jejunal segments (rabbit). We (78) studied the response in greater detail using a colon strip (rat) suspended in a sensitive strain-gauge tensometer and found that the increase in tension and the duration of response are proportional to the degree of reduction of Na_o . Dodd & Daniel (49) observed a similar immediate increase in the tension of an aorta strip following a reduction in Na_o .

The sudden reduction of Na^+ in the medium must at once unbalance ionic equilibrium across the smooth muscle cell membrane. The restoration of equilibrium, while still retaining electroneutrality in each compartment, may require a migration of positive ions from within the cell to the exterior. Since K ions are the only ones freely available for this they must shift outward (31, 32). The increase in tension recorded may be primarily related to the applied reduction of the Na gradient, Na_o/Na_i , or perhaps to an induced K^+ efflux from the cell.

We may suppose that, with time, the Na gradient is gradually built back up toward its basal state as Na is actively but relatively slowly extruded. Thus, when fully equilibrated, tissues in a low Na medium contain a reduced intracellular Na concentration, Na_i . Working with guinea pig taenia coli, Holman (118) has shown that at this stage the tissue still responds normally to stimuli, but Bohr *et al.* (13) claim hyperresponsiveness for the vascular strip. Daniel's group does not agree with this (49). When such tissues are equilibrated in very low levels of Na_o , however, all agree that they become first hyposensitive and finally unresponsive (49, 116, 118, 147, 188, 189). This suggests that the response falls off either because Na_i reaches some critical level or that Na_o/Na_i has itself fallen below some critical value.

The observation that tone or responsiveness or both decline after equilibration in very low Na_o seems quite uniform. The experiments of Dodd & Daniel (49) and Yamabayashi & Hamilton (214) show that the phenomenon applies equally well to vascular smooth muscle. It appears, however, that a fairly extreme reduction in Na_o is necessary to elicit this change and, since techniques vary, there is no uniform

answer concerning the absolute level at which the hyporeactivity occurs. Indeed this level may also vary in different types of smooth muscle (43). We shall later see whether the decline in responsiveness after equilibration in low Na media can be related to a reduction in the Na_o/Na_i gradient.

The time used by various workers for equilibration of their tissues varies over a wide range. This may well condition the responses obtained, since all tissues incubated in vitro for any length of time (in hours) take up Na and water and may extrude some K (165). Put another way, these tissues fail to maintain a normal sodium gradient. This process is accelerated by cooling and is more marked in artificial than in natural media, for example, plasma.

Despite the detailed differences between the experimental results with various smooth muscle types, we may conclude that, in general, an induced reduction in the sodium gradient produces an immediate increase in tension, while the continued presence of such a low gradient leaves the tissue less primed for the next stimulus, that is, hyporesponsive. Several additional observations now fall into line and a few of these may be dealt with at this point. Hughes *et al.* (120) found that rat uterus immersed in normal Krebs solution for 3 hours gained Na_i , as do all tissues, and became less responsive to test doses of histamine. We have incubated dog femoral artery in Krebs solution at 0°C overnight, a situation in which the cells must gain Na (165), and in the morning find the tissue contracted and totally incapable of responding to drug stimulation. Rewarming to 37°C, the standard procedure for re-extruding Na, relaxes the tissue and restores its responsiveness. McDowall & Zayat (145) have concluded that smooth muscle (uterus) takes up sodium during drug-induced contraction and in this state is less responsive to stimulation.

McDowall & Soliman (144) suggest that the post-stimulatory refractoriness is due to difficulty in repriming the cell by extruding Na. In brief, they relate unresponsiveness to the simple increase in Na_i and support this idea by the fact that responsiveness can be quickly restored to a refractory uterus strip by reducing Na in the medium. Three facts militate against this oversimplified explanation. In the first place, the acute reduction of Na in the medium can be expected to facilitate Na extrusion but only during the prolonged equilibration period. In fact, however, the reduction of Na_o restores responsiveness at once. In the second place, as we have pointed out earlier, the sudden reduction of Na_o immediately unbalances

the cell's ionic relation with its environment and may demand an efflux of K ions; this may be the basic process. This is supported by the fact that under similar circumstances, responsiveness can be as well restored by increasing K in the medium. In the third place, as described above, hyporesponsiveness occurs also in extremely low Na media when Na_i must necessarily be very low rather than high as after stimulation. Clearly, however, a reduction in the Na gradient is common to both hyporesponsive situations.

If an increase of tension in smooth muscle is ordinarily associated with a shift of Na from outside to within the cell as McDowall & Zayat (145) have suggested for uterine muscle and as we shall later suggest is a general process, we can distinguish in this the importance of the Na gradient. Thus, we (78) have shown that contraction of a colon strip, induced by a variety of agents, can be aborted by adding Na to the medium. This procedure affects only Na_o and not Na_i and thus directly implicates the Na gradient in the induction of the tension increase and not the simple intracellular gain in Na considered alone. We shall later associate these changes with K distribution as well.

There is reasonably consistent evidence concerning the events following exposure of a smooth muscle strip to a medium containing supranormal Na concentration. If the concentration of Na is high enough, the first response appears to be an increase of tension which is sustained for some minutes (10 or so) and then declines to subnormal levels as equilibration proceeds. This has been shown to apply to guinea pig taenia coli (116) and to the dog aorta strip (214). The increase in tension can be partially but not entirely attributed to an increase in osmotic pressure of the bathing solution. Other authors who did not raise Na_o quite so extremely noted no change in tension, but agree that tissues so exposed become hyporesponsive to drug stimulation. We (78) recorded such a decline in reactivity of the colon strip following exposure to even moderate elevations of Na_o. Williamson & Moore (209) observed that a rise in Na_o and a fall in K_o, either individually or in combination, caused a lessened response of the isolated rabbit aorta strip to norepinephrine. Similar findings were reported earlier by Bohr *et al.* (13). We cannot account for the observation of an increase in responsiveness to epinephrine under similar circumstances (214).

Although the complexity of the procedures and responses used to study this problem almost defy rational interpretation, several fundamental facts do emerge.

1) Vascular smooth muscle, like other types of smooth muscle, responds to sudden reduction of Na_o with a temporary increase of tension proportionate to the degree of change in the medium. Tension declines as equilibration proceeds.

2) After equilibration in moderately low Na_o media, the responsiveness of vascular smooth muscle is unchanged or increased. At critically low levels of Na_o the tissue becomes hyporesponsive.

3) Vascular smooth muscle exposed to high Na_o may show a temporary increase in tension, but very high levels of Na are required for this.

4) After equilibration in high Na_o media the responsiveness of vascular smooth muscle is substantially reduced.

5) Studies of the effects of ions must distinguish between immediate effects which reflect a temporary instability and later effects which depend on the new equilibrium.

EFFECTS OF MANIPULATION OF K IN THE MEDIUM. Although the procedures and responses vary a good deal, it has been found that most types of smooth muscle increase their tension upon exposure to a potassium-enriched environment. The older literature has been reviewed by Evans (60) and the more recent by Goffart & Bacq (91). The latter authors indeed go so far as to point out that the potassium-induced contraction can be used as a basic procedure for the study of agents which enhance (sensibilize) or inhibit the response. The following reports are typical of the studies carried out and of the results obtained.

Holman (118) studying guinea pig taenia coli reported that at first a reduction of K in the medium produced little effect. After a few minutes, however, tension began to fall and on prolonged exposure low levels were reached and maintained.

Exposure of the uterus of the rat, guinea pig, rabbit, or cat to an elevation of K in the medium produces an immediate contraction (190). So, too, the intestine strip shows an immediate increase in tension (3, 118, 147, 204). Cantoni & Eastman (28) observed that the temporary depression which follows maximal contraction of the guinea pig intestine exposed to histamine, acetylcholine, pilocarpine, barium chloride, or Mecholyl can be overcome by a small increase of K in the medium. Similarly, Hazard & Cornec (107) found that small amounts of K increased the response of the rat duodenum to acetylcholine.

In general, vascular tissue follows similar patterns. As early as 1926 Gellhorn (90) attempted to place a series of cations in a rank order based on their effects

FIG. 3. Tension changes in carotid artery strips on exposure to different concentrations of A, K^+ and B, Cs^+ . Concentration of the cation in millimolars appears at the right of each line. [From Laszt (135).]

on an isolated aorta strip. He pointed out that the addition of Li^+ relaxed the strip and that Na^+ produced no obvious change, while NH_4^+ , Cs^+ , Rb^+ , and K^+ in that ascending order caused increasing degrees of contraction. He did, however, use fairly extreme quantities, adding in each case 3 ml of an isotonic concentration of the chloride to 10 ml of Tyrode's solution. In effect he raised the K concentration of the medium to about 50 meq per liter.

Furchgott & Bhadrakom (88), in the course of pioneer studies which established the rabbit aorta strip as a standard test object, observed the effects of more moderate increases in K_o . They noted that contraction followed if the K level was raised to three- or fourfold normal. The addition of smaller amounts of K, sufficient only to double that of the normal medium (Krebs), did not cause visible contraction but did potentiate the response to low doses of epinephrine.

Bohr *et al.* (13) confirmed and extended these findings. Using the Furchgott procedure, they noted a marked increase in the response of the aorta strip to norepinephrine when the medium K was doubled. Additionally, they observed a marked and progressive reduction of responsiveness in a K-free medium. More recently, Barr *et al.* (10) studied the responsiveness of dog carotid artery strips stored in the cold and then rewarmed. Stored in the cold, 4°C, these strips, like most tissues (165), gained Na_i and lost K_i , and with this their responsiveness declined. The recovery of maximal responsiveness was roughly parallel to the steady-state K reaccumulation during the progression of rewarming. Williamson & Moore (209) observed that the sensitivity of the rabbit aorta strip varied

with changes of K in the medium in a manner inverse to Na. Thus, lowering Na or raising K, singly or in combination, increased the sensitivity to norepinephrine. Conversely, raising Na or lowering K, singly or in combination, decreased the norepinephrine-induced contraction. Dodd & Daniel (49) also pointed out that contractile responses increase in a high K medium. They observed a transient increase of sensitivity in a K-free medium as well, but this rapidly yielded to the usual reduction in responsiveness observed by most workers.

Laszt (133-135) has recently produced unequivocal evidence relating tension and the concentration of K in the medium (fig. 3). Using a carotid artery strip (specified only as from "cattle") this worker has shown that the stepwise elevation of K_o produces a stepwise increase in tension. The threshold concentration of cesium (5 mM) or rubidium (10 mM), which can similarly induce a contraction when added to the medium, is less than that required for potassium (30 mM), and this Laszt considers to be direct evidence relating the effect to ion size. Similarly, the tension induced by equal concentrations of cesium, rubidium, and potassium chloride shows the same dependence on rank order. The interpretation which this investigator places upon these findings argues that the tension increase is a function of the rate at which Cs^+ , Rb^+ , or K^+ can move into cells. This neglects the fact that the ability of ions to cross cell membranes is not an exclusive function of their hydrated radius (see table 3).

One group of observations stands alone and contrasts sharply with the examples cited above. In these a reduction of K_o is reported to be associated with

hyperexcitability (140), while an increase in K_o reversibly abolishes the ability to contract (47). These two rather baffling reports, although stemming from different authors, are united in one major respect: the artery preparation was driven electrically rather than by means of a known physiologically active mediator.

Although once again we find that it is difficult to equate the complex procedures used and the complex results obtained, several fundamental facts emerge.

1) Vascular smooth muscle, like other types of smooth muscle, responds to the sudden reduction of K_o with little immediate change.

2) As equilibration in low K_o media proceeds, the responsiveness of vascular smooth muscle and its basal tension progressively decline to reach a new low level which is steadily maintained for long periods. The experiment of continuing to lower K_o by successive washout has apparently not been attempted.

3) Vascular smooth muscle exposed to high K_o (at least fourfold normal) shows an increase in tension proportionate to the increase in K_o , and this is usually sustained. Responsiveness too is increased in high K_o media.

4) Time is an important variable in the responses studied—too often an insufficiently considered variable.

5) In general, there is a suggestive inverse relation between K_o and Na_o .

Evidence from Studies of Resistance in Regional Vascular Beds

EFFECTS OF NA INFUSIONS. It is exceedingly difficult to attempt to alter only one constituent of a perfusing solution in an *in vivo* preparation and still remain within the bounds of physiological decency. Even so, considerable progress has been made in demonstrating that at least some of the *in vitro* observations have important implications for vascular homeostasis. We shall now examine the major lines of these investigations, noting especially where they are consistent with the evidence already cited.

All workers who have infused Na salts into the arterial circulation have observed peripheral vasodilatation. Eliakim *et al.* (56) observed a fall in systemic blood pressure in the dog on injecting 1 ml per kg of 20 per cent NaCl fairly rapidly. We (78) observed that Na salts depress diastolic and systolic blood pressure in the rat even in the presence of a simultaneously administered pressor agent. Katz & Lindner (125) perfused the coronary arterial circulation in the dog with defibrinated blood in a classic

FIG. 4. Relation of serum $[Na^+]$ in venous outflow to vascular pressures and resistances in the dog forelimb. Average of 11 animals. Ten per cent NaCl infused into brachial artery at 0.6, 1.0, 2.3, and 0.0 ml/min in that order. [From Haddy (101).]

series of experiments and observed that even fairly small additions of Na produced vasodilatation.

Marshall & Shepherd (148), in a beautiful series, used the newly developed ultrasonic flowmeter to monitor flow in the femoral artery of the dog and studied changes in limb resistance in response to Na salts. They found that the rapid injection of 2 ml of 10 to 20 per cent NaCl produced vasodilatation. The same effect was obtained with a continuous infusion of the same solutions at 2.3 ml per min. A series of other salts (citrate, lactate, bicarbonate, acid and alkaline phosphate) all produced the same effect. Binet & Burstein (12) obtained similar results in the dog limb isolated from the circulation of the rest of the body, except as perfused under control from the systemic circulation through a constant pressure pump.

Haddy and his associates have used perhaps the most detailed and elegant technique to study this same problem. Basically, these workers perfuse the forelimb of the dog with arterial blood rerouted from the femoral artery. The connecting polyethylene tubing uniting the femoral to the brachial artery passes through a constant output pump which operates by intermittent compression of the tubing. Pressure

FIG. 5. *A*: changes in renal vein flow, F_{RV} , and renal artery pressure, P_{RA} , with perfusate composition changes. T_{RV} = temperature of renal vein outflow. [From Harvey (104).] *B*: effect of hypertonic saline solution on blood flow through femoral artery measured with ultrasonic flowmeter. [From Marshall & Shepherd (148).]

is monitored by means of fine cannulae passed into the vascular tree at several points distal to the pump so that a detailed description of the resistance of the various segments of the circulation can be compiled. Haddy (101), too, found that amounts of NaCl, insufficient to alter systemic pressure, produced arteriolar dilatation in the dog forelimb.

Unfortunately, it is not possible to elevate plasma Na concentration in the perfusing blood without at the same time raising its tonicity. Marshall & Shepherd (148) first noted this as an experimental defect and found that they could obtain a similar degree of vasodilatation by infusing dextrose and urea matched for tonicity to their sodium salts and concluded that the mechanism of vascular relaxation was uncertain. Muirhead *et al.* (154) had earlier noted this effect of hypertonic infusions. This point led Overbeck & Haddy (156) to restudy the problem. They found that hypertonic solutions of NaCl, Na_2SO_4 and Na_2HPO_4 , which produced the same final serum Na concentration, evoked decreases in limb vascular resistance in parallel with their actual tonicity. Equally hypertonic infusions of Na_2SO_4 , and NaCl, irrespective of the amount of Na supplied, evoked equal decreases in small vessel resistance. They concluded that the addition of Na apparently had little or no independent effect apart from that of its tonicity. On the other hand, these same workers (102) have obtained some evidence that a reduction

of Na in the perfusing medium is slightly vasoconstrictive and decreases the caliber of the small vessels. Harvey (104) and Read *et al.* (164) have studied the effects of hypertonic solutions on the renal vascular bed and have arrived at the same conclusion regarding the relation of hypertonicity of the infusion and its vasodilatory effect.

These findings are in substantial agreement with those obtained with vascular and other smooth muscle strips studied *in vitro*. It will be recalled that following exposure to high Na_o such tissues may show a temporary increase in tension, but very high levels are required for this. On the other hand, after equilibration in such high Na media, tension is usually lower than normal and responsiveness of these tissues is reduced, and this obtains *in vivo* as well. Thus, following perfusion of the rat with Na salts we (86) found the blood pressure responses to norepinephrine and to Pitressin sharply reduced. Haddy (101), in more precise studies, has shown this to be due to a reduction in the responsiveness of peripheral vessels to both pressor and depressor agents. Since this effect persists, it may not be directly related to the osmotic effect of the hypertonic solution.

It should be emphasized that an osmotic effect produced by infusing a hypertonic solution cannot, in fact, be dissociated from an ionic effect. The withdrawal of water from cells causes a proportionate

increase in both Na_i and K_i . We shall deal with the quantitative aspects of this type of shift later.

EFFECTS OF K INFUSIONS. Attempts to link the effects observed in vitro to in vivo responses of vascular tissue have necessarily been limited in scope. This again reflects the technical problems limiting such exploration.

Mathison (149) long ago produced what is still one of the best pieces of work on this subject. He injected a few milliliters of $M/7$ (isotonic) KCl into the arterial circulation of the cat. A rise in blood pressure followed at once; this was also obtained in the decerebrate, spinal, or spinal-pithed animal. The effect was not of cardiac origin and was only partly due to excitation of vasomotor centers, since a considerable rise of pressure was still obtained after ergotoxine. This author paid careful attention to tonicity, anion control, and pH. He pointed out also that peripheral vascular relaxation rather than constriction followed the injection of less concentrated solutions beginning at $M/11$. Hoff *et al.* (115) obtained much the same result.

Hazard & Quinquaud (108) carried out an exceedingly nice pharmacological study of the pressor effect of intra-arterially injected KCl. They showed that a large part of the effect was due to adrenal medullary discharge. Then, using a series of blocking agents, they came to the conclusion that a significant part of the vasoconstrictive action of K was directly exerted on vascular smooth muscle.

McKeever and associates (146) perfused the left coronary in the dog with blood from a donor animal, interposing a constant output pump in the line (cf 101). KCl was then added at constant rate to raise plasma K from 2 to 20 meq per liter. Except at the very lowest concentrations the infusions produced a transient dilatation of large and small arterial segments lasting for about 1 min, followed by a more sustained constriction. Still higher concentrations were entirely constrictive, but the degree to which an adrenal discharge may have contributed was not assessed.

Emanuel *et al.* (58) have carried out a careful analysis of the changing pattern of resistance in the different segments of the dog forelimb during infusion of K salts and have correlated their findings with systemic and local measurements of serum Na and K. Small vessel resistance decreased at all infusion rates. By contrast, arterial resistance did not change at lower rates and then, as the rate increased, gradually began to show an increase. The net effect of these

changes was an over-all fall in resistance at low rates and a rise at higher ones. The primary phenomenon held for increases in serum K up to about 8 meq per liter, at which point the secondary net constrictive effect appeared. The arterial constrictive phase may be in large part related to adrenal discharge. These results were similar for the chloride, nitrate, lactate, and acetate. They applied equally well to the renal vascular bed (178). Even these moderate elevations of K_o reduced the sensitivity of the peripheral vasculature to challenging doses of pressor and depressor agents.

The work of this group satisfactorily explains the phase of falling peripheral vascular resistance noted by all authors who have infused small amounts of KCl. It also shows that K does not produce smooth muscle vasoconstriction in the physiological range and agrees in this with in vitro studies. It leaves unexplored, and correctly so, the effect of high, unphysiological amounts of K which are vasoconstrictive in vitro. This latter point has great theoretical importance if a change in membrane potential is involved in peripheral vasoconstriction. Unfortunately, the experimenter cannot explore the problem in vivo, for although high K infusions do not, like Na, raise problems of osmotic pressure they do produce adrenal, cardiac, and nervous effects which presently defy rational interpretation.

Speaking critically, the perfusion of regional vascular beds is not a totally satisfactory approach to the problem. Technically, many of the procedures give detailed information concerning the responses of each segment of the vascular bed and for this are most satisfactory. The problem resides not in this facet of the approach but in the attempt to alter a single variable in the medium while still perfusing with whole blood. Such a situation cannot be fully controlled. Using the Na and K electrodes we have found many times that the solution we thought was presented to the cells was not the same as the solution the cells actually met. To interpret such perfusion data fully requires information about the Na, K, and Ca levels actually attained, together with an estimate of pH.

Evidence from Measurement of Na and K in Relation to Blood Pressure

MEASUREMENT OF NA AND K IN CHRONIC HYPERTENSION OR HYPOTENSION. *Deoxycorticosterone (DCA) hypertension.* Ledingham (137, 138) studied the relation of Na and K partition to blood pressure in a series of

DCA-treated rats using inulin to estimate water distribution. Unfortunately, he analyzed only skeletal and cardiac muscle and hence his report of an absence of correlation must be treated cautiously. Despite his own rather negative conclusion, if we assume that his methods can only distinguish extremes and not transitional stages, his tables show several striking features. Blood pressure in the control-adrenalectomized group averaged 86 mm Hg, while the adrenalectomized saline-treated group reached 114 mm Hg. The two groups attaining the highest pressure were likewise adrenalectomized and received either DCA-saline or DCA-saline-cortisone and had average blood pressures of 191 and 221 mm Hg, respectively. Both Na_o and Na_i values were highest in these groups and the Na_o/Na_i gradients lowest. Again, K_o was lowest in both these groups, while K_i did not fit any pattern. The value for K_o is perhaps particularly important, since it has also been reported as a finding in the accelerated phase of essential hypertension in man (111, 131). Low levels of serum Na have also been noted at this stage of the disease (46).

Woodbury & Koch (211) also noted in the rat that DCA and aldosterone produce an increase in skeletal muscle Na which, judging by measurements of chloride space, is largely intracellular and represents an increase in Na_i . Potassium was little altered. Unfortunately, blood pressure was not measured. Ferrebee *et al.* (62), using more laborious techniques, had long ago shown that DCA in the dog caused a gain in Na_i at the expense of K_i . Cier and co-workers (29) and Gross & Schmidt (99) also claimed that DCA increases Na_i in skeletal muscle.

Insofar as blood pressure regulation is concerned it is more important to attempt to estimate the effect of DCA on Na and K in a representative of vascular tissue. The aorta has so far been the only tissue amenable to study and here, by and large, the evidence points the same way. The classic and most quoted paper in this field is that of Tobian & Binion (196), who reported an increase in both Na and K in the aorta of rats made hypertensive with DCA. From estimates of the extracellular space (based on chloride measurements) they believed that most of the increase represented a true intracellular gain. Tobian & Redleaf (199, 200) reaffirmed these findings in later studies.

Daniel & Dawkins (40) claimed that aorta electrolyte changes demonstrable in early DCA hypertension disappeared later in the disease. In early hypertension they noted a tendency for a gain in Na_i but, more

significantly, for K depletion in hypertensive rats under treatment compared with normotensive also under treatment. Most recently, Laszt (133) also reported a gain in aorta Na following DCA treatment.

By and large it would seem that DCA causes a gain in Na in both skeletal muscle and in aorta in the rat; a goodly part of this gain probably represents a true intracellular increase, but with the methods so far used it is difficult to assess just how much is actually intracellular. The gain in Na is apparently not accompanied by a parallel gain in water, so we are fairly safe in inferring from all authors that intracellular Na concentration, Na_i , is elevated. All reports uniformly fail to provide us, however, with simultaneous estimates of Na_i of the aorta and Na_o of the medium, which is a crucial piece of information. This same lack of information tends to nullify Laszt's claim (133) that blood pressure cannot be related to the total Na content of the aorta. In our opinion, it would be exceptional if blood pressure could indeed be related to one such simple parameter as that.

Other hypertensive states. We have considered DCA separately because of its obvious effects on electrolyte metabolism which might perhaps be considered to make it a special case. We turn now to a more general review of the findings for Na and K analysis in a divergent series of conditions united only by the fact that a sustained hypertension is a common feature.

Ledingham (139) has recently reviewed this and decided that the only common feature in these varied states is the elevated blood pressure itself. His negative view is based on his findings in hypertension induced by DCA, cortisone, renal artery constriction, and bilateral nephrectomy (136–138). As described above, he may have overemphasized the negative aspects of his data. It is unfortunate too that this conclusion should have been arrived at without any attempt to measure electrolytes and water in vascular tissue.

In their original report Tobian & Binion (196) considered renal as well as DCA hypertension in the rat. Aorta Na and K were both elevated following renal constriction in rats developing hypertension compared to animals remaining normotensive after the same operation. Tobian (192) extended this work by using a low sodium diet to control the blood pressure rise of animals with renal constriction and found the changes directly related to the presence or absence of hypertension.

More recently Tobian & Redleaf (200) found that rats with post-DCA sustained hypertension, with adrenal regeneration hypertension, and with the

hypertension that may persist after excision of an ischemic kidney all show an increase in aorta Na and K. This increase seemed to them to represent a true gain in Na_i and K_i . There is a suggestion that these studies may be pertinent to the problem of hypertension in man, for Tobian & Binion (195) found an increase of both Na and water in the renal arteries of human hypertensives. Na was increased more than water, but the technique used cannot distinguish intracellular from extracellular locations. Not too much weight should be given this type of study, however, for as all workers in the field know, electrolytes may exchange rapidly across vessel walls both immediately preceding and certainly after death.

In general, experiments in many laboratories support the thesis that Na and K in tissues are altered in hypertension, but the emphasis shifts now to the one, now to the other. Thus, Eichelberger (53) long ago measured an increase in Na and fall in K in the skeletal muscle of dogs made hypertensive by renal constriction. Assuming an extracellular position for chloride there appeared to be a true rise in Na_i and fall in K_i . Laramore & Grollman (132) found a general rise in tissue Na and water and a fall in K in the later stages of renal hypertension in the rat. Later, however, Grollman (96) found the same quantities unchanged in hypertension produced as a late sequela of choline deficiency. More recently Koletsky *et al.* (129) analyzed the mesenteric arteries of rats with acute renal hypertension and also found a gain in Na, K, chloride, and water. These authors, however, cautiously refrained from attempting to partition the electrolytes on the basis of chloride space.

In agreement with Tobian and associates, Freed *et al.* (70) found an elevation in aorta K in renal hypertensive rats but a less well-defined increase in Na. The reduction of the hypertension by dietary K deprivation was followed by a proportionate decrease in aorta K, and the return to hypertensive levels on refeeding K was accompanied by a return rise in aorta K. On examining the data, however, it is evident that the increase in aorta K occurs in rats with renal constriction whether or not the pressure goes up. This same inconsistency was noted by Tobian & Binion (196).

Laszt (133) does not find an increase in aorta Na at all consistent with the presence of hypertension in rats, but claims the rise of K to be so.

Houck (119) pointed out that dogs maintained in good balance for 5 to 111 days following bilateral nephrectomy show a gain in tissue Na and fall in K

despite relatively normal extracellular values. This apparently indicates an association of their sustained hypertension with an elevation of Na_i and fall in K_i . Greene & Sapirstein (95) found an increase in total body Na in rats made hypertensive by subtotal nephrectomy. Haight & Weller (103) studied rats made hypertensive by chronic high salt feeding; they found hypernatremia and an increase in skeletal and heart muscle Na and K especially pronounced in the hypertensive rats but no conspicuous differences in aorta electrolytes.

Other sustained abnormal blood pressures. The regularly observed fall in blood pressure in Addison's disease or following adrenalectomy requires no comment. Among other phenomena, it is associated with a reduction of tissue Na from both intracellular and extracellular compartments (30, 52).

Freed *et al.* (69) examined the relation of plasma to aorta Na and K in rats made hypotensive by K deprivation. Both Na and K declined in plasma as well as in the aorta, although the authors stress only the change in K. Tobian (191) found that rats on a low Na diet lose a sizeable amount of aorta Na, while serum Na may actually rise a little. Although blood pressure was not measured it was assumed to tend toward lower values.

Trauma may lead to a "posttraumatic sodium-potassium shift" during which plasma Na falls and K rises. This is associated with hypotension (186).

MEASUREMENT OF Na AND K IN ACUTE HYPERTENSION OR HYPOTENSION. Although investigation of the association between acute changes in blood pressure and electrolyte exchanges is comparatively recent, the findings are more clear-cut than any we have so far considered. The independent findings from different laboratories all fit together nicely even though interpretations vary. Since this approach bears directly on the relation of ions to vascular smooth muscle tension, the facts obtained must form the basis of all theoretical discussion. Accordingly, we shall present these facts in some detail.

Perhaps the earliest report of a relation between ionic concentration in the serum and a pressor agent was that of D'Silva (50) in 1934. He reported that, in the cat, following the intravenous injection of 50 μg of epinephrine or 10 units of Pitressin intravenously serum K rose sharply as much as 3 meq per liter within 1 min. Since these massive doses of the order of 10 μg per kg epinephrine and 2 units of Pitressin per kg also caused a rise in blood sugar, this author related the K rise to the glycogenolytic effect

FIG. 6. *A*: influence of anesthesia on plasma $[K^+]$ rise induced by epinephrine in the dog. Arrhythmias and time of their occurrence shown by horizontal lines at top of figure. *I.T.* = ventricular tachycardia. *B*: effect of a series of sympathomimetic amines on plasma $[K^+]$ in the dog. *I.T.* = ventricular tachycardia, *V.E.X.S.* = numerous ventricular extrasystoles. [From O'Brien *et al.* (155).]

of the injections rather than to the blood pressure effect. This explanation for the rise of K remained unchallenged and uncritically accepted for almost two decades.

O'Brien *et al.* (155) in 1953 obtained beautiful curves showing the rise of plasma K after rather lower doses of norepinephrine, 5 μ g per kg, in dogs. Although norepinephrine does not have any marked effect on the mobilization of glucose and although these authors pointed out that it is blocked by Dibenamine, which would not block a glycogenolytic effect, the original explanation still persisted. O'Brien and his associates also pointed out that the choice of anesthetic modified the effects, ether being the worst for blurring the effect, cyclopropane affecting it least, Nembutal almost as good as cyclopropane. These important observations were unfortunately ignored by most later workers including ourselves. (In our more

recent studies we have found the effects considerably sharpened if a barbiturate mixture is used instead of ether.)

Muirhead *et al.* (153) in the next year restudied the problem. They gave norepinephrine by infusion in total doses of 1 to 7 mg per kg in 50 to 180 ml of saline over periods ranging from 20 to 50 min. Concerning their results they wrote: "In many of the experiments the sodium curve represents an approximate mirror image of the blood pressure curve. In most of the experiments the changes of potassium were not as pronounced as those of sodium. In addition there seemed to be little if any correlation between blood pressure and plasma potassium. The latter is in contrast to the variations in sodium levels which reflected even sudden changes in blood pressure." No real change in radiosulfate space or in chloride concentration was observed. These observations did not have the impact they ought to have had for the doses used were very large.

Tobian & Fox (197) then approached the problem directly and analyzed segments of dog femoral artery before and after infusing norepinephrine sufficient to maintain a blood pressure elevation for 30 min. A consistent fall in artery K and a less consistent gain in Na was observed. These changes were believed to represent a fall in K_i and rise in Na_i , but the authors tended to underestimate the importance of the Na change since it was less consistent. In our view, the difficulties inherent in such tissue analysis and their basic range of error make it highly significant that even this trend for a sodium increase was observed; in fact, a sizeable Na gain was found in 9 of 12 dogs. In the light of later evidence, we must conclude that a fall in K_i and a real gain in Na_i , probably with water, actually did occur.

Shortly thereafter, following up the possibility that Pitressin might have an extrarenal action, we observed that this agent caused a shift of water out of the extracellular space in the bilaterally nephrectomized rat. In a more detailed study, we found that Na also left the extracellular space in association with, but in excess of, water so that there was a measurable fall in plasma Na concentration (82). The relation of dose to response was presented at this time and the correlation of the shifts with blood pressure noted. In interpreting these exchanges of salt and water, we took into account the changes which other workers had previously observed to follow norepinephrine administration and hypothesized that both sets of observations could be related by a general rule that blood pressure regulation depends on the

sodium transfer systems, broadly defined. The rise in plasma K following Pitressin administration was considered an integral part of the phenomenon, but left aside from this first theoretical approximation for later consideration.

In these first studies we overestimated the absolute magnitude of the water shift that follows Pitressin administration. This was corrected in subsequent studies. The effects of norepinephrine on Na, K, and inulin space in the nephrectomized rat were then compared with those produced by Pitressin and again a net loss of extracellular Na was observed in association with the blood pressure rise (75). Pitressin in the large doses used caused a measurable fall in plasma Na indicating that Na moved in excess of water. With the techniques at hand (flame photometry, arterial blood sampling) no clear fall in plasma Na concentration taken alone was observed with norepinephrine, but a shift of Na and water was claimed on the basis of replicate experiments in which extracellular sodium was calculated. Angiotensin was then compared with Pitressin in the nephrectomized rat (76). Both agents given intravenously produced a measurable fall in plasma Na concentration and a fall in extracellular fluid volume (inulin) associated with the rapid rise of blood pressure. While Pitressin produced a measurable increase in extracellular K, angiotensin did not.

It was clear at this time, at least for norepinephrine, that the fall in Na and water and the rise in K which we were measuring in the extracellular compartment of the rat corresponded qualitatively to the gain in Na and loss in K which Tobian & Fox (197) had measured in the femoral artery of the dog. Daniel *et al.* (41) then injected a pressor dose of norepinephrine within the physiological range, 1 μ g per kg, in the rat. They found that the aorta was rapidly depleted of K while Na tended to increase. This is surprisingly good confirmation in view of the fact that the Na shift is probably partly obscured by a movement of water which these workers could not measure.

Subsequently, this group (42) studied the effects of Pitressin and isoproterenol (isopropyl norepinephrine, a peripheral vasodilator) on aorta electrolytes in the rat. They concluded from the variations in aorta sodium that during blood pressure changes, Na moves into (rising blood pressure) and out of (falling blood pressure) vascular muscle cells. Since they were dealing with the aorta, an outward movement of K occurred only with those drugs known to cause an aorta strip to contract. They pointed out, however, that the total amount of Na which we had reported to

leave the extracellular space could not possibly be accommodated within the cells of the vascular tree. This difficulty has now been satisfactorily resolved by our observation that skeletal muscle also takes up sodium under the influence of Pitressin (85).

In the rat, studies of changes in plasma Na, K, and inulin space during changes in blood pressure are technically difficult, since each step in drug, dose, or time interval requires the use of separate groups of animals. To circumvent this, as well as to extend the observations to the dog, we studied the problem in the bilaterally nephrectomized dog using norepinephrine, isoproterenol, angiotensin, and Pitressin (73). We found that the calculated extracellular Na (product of inulin space and plasma Na) declined as pressure rose and increased as it fell; the two measurements consistently formed mirror images. Calculated extracellular K in general moved inversely to Na and hence in parallel with the pressure except in the case of angiotensin where, as in the rat, no K shift was found.

In the case of norepinephrine, the simple measurement of plasma Na was an inconsistent index of Na movement, since the real decrease in this ion is partially masked by a movement of water in the same direction. For the same reason, K concentration is a consistent but inaccurate estimate of K movement, since the change is magnified by inverse movement of water. In the case of Pitressin, although both Na and water move out of the extracellular compartment, the Na shift is well in excess of the water so that, if the dose is adequate, a fall in plasma Na is readily observed. These findings are remarkably similar to those obtained in the rat.

Warren (205) has recently studied the effect of Pitressin on Na, K, and inulin space in the trained, conscious, intact dog. He observed similar exchanges to those previously reported in the nephrectomized dog even though he used considerably smaller doses of Pitressin (30 mU/kg as a single i.v. injection versus 200 mU/kg/min for 10 min by infusion).

Recently the Na and K electrodes have been applied to this problem. In the first experiments we used only a sodium electrode interposed into the femoral artery of the dog (80). The aim was to determine whether pressor and depressor agents actually shift Na levels as blood sampling procedures indicated. The result was unequivocal; the pressor response to norepinephrine, epinephrine, and angiotensin was regularly accompanied by a fall in electrode potential indicating a fall in sodium concentration, or more precisely, sodium activity. In terms of degree of change, time course, and duration of effect, each agent

FIG. 7. Changes in extracellular Na and K associated with blood pressure changes in the dog.
[From Friedman *et al.* (73).]

produced its own characteristic pattern. The depressor response to acetylcholine, histamine, and isoproterenol was accompanied by oscillations in the tracing which tended to be inverse to those observed with pressor agents. Later, in a similar arrangement using two electrodes, norepinephrine was shown to produce a rise in (K^+) inverse to the fall in (Na^+) (81).

The technique for electrode monitoring of (Na^+) and (K^+) in flowing blood was then modified after Haddy so as to control flow rate through the electrode as well as through the vasculature of the limb (122). The femoral artery of the dog was interrupted by a length of polyethylene fed through a Sigmamotor pump. The femoral vein was similarly lengthened and passed through a smaller division of the pump. The venous outflow passed through Na and K cannula electrodes in a shielded enclosure. This arrangement ensured not only a constant limb inflow but also the passing of a proportion of the venous outflow at a constant rate past the electrodes. Quantitative measurements could also be made, since calibrating solutions could be injected into the venous tubing proximal to the pump. One pressure transducer was inserted on the arterial side between pump and limb and another into a brachial artery. Small amounts of

vasoactive agents sufficient only to activate the limb vasculature without producing any noticeable systemic effects were used.

In general, limb vasoconstriction induced by norepinephrine or epinephrine was associated with a fall in blood (Na^+) and often with a rise of (K^+). Larger doses tended to produce a biphasic response in (Na^+), that is, an initial transient rise preceding the fall. Vasoconstriction produced by serotonin or angiotensin was associated with similar (Na^+) change unaccompanied by any consistent (K^+) deflection. Vasoconstriction produced by Pitressin was associated with a fall in (Na^+) and consistent rise in (K^+), both noticeably greater in degree and duration than with other agents producing an equal degree of vasoconstriction. Limb vasodilatation induced by isoproterenol, acetylcholine, or histamine was accompanied by a rise in blood (Na^+) without any consistent change in (K^+).

A full analysis of rates and relations of ion and water movement is clearly required. For the moment, we may conclude that the movements of Na and K associated with changes in blood pressure reflect changes in tension in the peripheral blood vessels.

Only one report disturbs the general consistency of this phase of the investigation. Headings *et al.* (109)

FIG. 8. Changes in blood (Na^+) and (K^+) monitored with the Na electrode ($\text{Na}/\text{K} = 250/1$) and K electrode ($\text{K}/\text{Na} = 5/1$) in the dog during A, systemic blood pressure rise induced with norepinephrine and B, limb pressure rise induced with norepinephrine. [A, from Friedman *et al.* (81).]

found that dog carotid artery rings stimulated electrically gained Na and lost K. Epinephrine, however, in an amount sufficient to produce the same contractile response did not produce these changes.

We may conclude that, in general, an acute increase in tension of vascular smooth muscle is associated with a gain in Na_i and a gain in water. There is a strong suggestion that in some instances, at least, the gain in water may overshadow the gain in Na and may also anticipate it. A loss in K from cells to environment is almost always observed. Similar ionic exchanges have been observed both in taenia coli and uterus during activity (16, 124).

These experiments give no information regarding the time relations connecting these phenomena nor do they suggest which event is cause and which is effect.

Evidence from Studies of the Relation of Electrical Activity to Tension in Vascular or Analogous Tissues

Bacq & Monnier (7) studied the relation of electrical activity to tension in a variety of smooth muscles obtained from the cat. They claimed that the laws common to all excitable tissues apply to smooth muscle as well. In their view the response to every excitation, in this case contraction or increase in tone, no matter how produced, is accompanied by a decrease in polarization. They considered the change in polarization to be the cause of the change in tonus. In accordance with theories current at that time de-

polarization was attributed to the exit of K^+ from cells.

Although Bozler (17) carried out the first basic studies of electrical activity in smooth muscle using modern techniques it remained for Bülbring and her associates to carry out the difficult task of defining the ionic basis of that activity. In 1954 data were presented for guinea pig taenia coli suggesting that tension is inversely, and spike frequency directly, related to the membrane potential (19).

We can summarize these first experiments in a simplified form. A resting membrane potential of $60 \pm 9 \text{ mV}$ fell to 43 ± 10 and spike frequency increased when the tissue was stretched (increased tension). Histamine induced a fall in potential from 58 to 40 mV while tension and spike frequency increased. Epinephrine induced an increase in potential and a decrease in tension and spike frequency. Acetylcholine caused a fall in potential and increase in spike frequency and tension. Shortly thereafter Bülbring (20) reported that the increase in rate of spike discharge was proportional to the increase in tension. Then, in 1955 (21), fluctuations in membrane potential were observed to be related to the spontaneous rhythm of the taenia coli strip and periods of depolarization associated with increased tension and increased rate of spike discharge alternated with periods of repolarization, reduced spike frequency, and lower tension.

From this basis Born & Bülbring (16) then proceeded to the still more difficult technical problem of

FIG. 9. Fluctuations of tension (*broken line*) and of radioactivity (K^{42}) appearing in washing solution (*continuous line*) of taenia coli during spontaneous activity *A*, before, *B*, in the presence of atropine 2×10^{-6} . [From Born & Bülbring (16).]

adding measurements of ionic exchange to the simultaneous monitoring of tension and electrical activity. By restricting their attempt to the simpler problem of measuring only K they succeeded quite elegantly and in so doing proved beyond doubt that basic ionic theory is generally valid, at least for the gut strip. They used K^{42} as tracer and analyzed the medium flowing past the tissue. Spontaneous activity was characterized by the parallel rise and fall of K efflux and tension so that as tension rose, K efflux increased and as tension fell, K efflux decreased. Similarly, histamine and acetylcholine produced contraction associated with a parallel increase in K efflux. Epinephrine, which causes relaxation of this particular preparation, seemed to do so by increasing K influx. The fall in membrane potential previously observed to parallel the increase in tension was evidently associated with an ionic shift here measured as K efflux. Presumably, if it had been technically feasible to measure, a primary sodium influx would have been recorded.

Born (15) then turned to a study of some of the metabolic problems concerned with contraction in smooth muscle and for the first time we find a firm separation of the relatively rapid changes in tension from the maintained changes which we recognize as *tonus*. The position is best stated by the author: "The development of tension by smooth muscle involves two mechanisms. One mechanism is responsible for

the immediate rise in tension which occurs when the muscle is stimulated and this mechanism continues to function in anoxia and in the presence of 2:4 dinitrophenol. The other mechanism is responsible for the sustained tension which the muscle shows, both spontaneously and following stimulation. This mechanism is abolished when metabolism is interfered with, e.g., by depriving the muscle of glucose or of oxygen, or by exposing it to 2:4 dinitrophenol."

Later studies of electrical activity have rather tended to cloud the picture. Bülbring & Lüllman (22) demonstrated that spike frequency and tension could be dissociated. Using dinitrophenol they showed that spike frequency could be made to increase or decrease without particular reference to tension changes. The inverse relation of tension to membrane potential still held under these circumstances, however, so that at this point we might tend to disregard spike activity. This idea is reinforced by Holman's observation (117) that the addition of KCl to the medium bathing a taenia coli strip increases tension and decreases the membrane potential. Further, at concentrations above 20 meq per liter, the relation of K_o to membrane potential is linear with a 33 mv slope per log unit change, an important fit with ionic theory although the low slope remains to be accounted for.

Burnstock & Straub (26) using an improved procedure, the sucrose-gap technique, verified the fact that K salts produced a membrane depolarization,

showed the importance of penetrability of the accompanying anion, and improved the relation of E_m to $\log K_o$ to yield a slope of 45 mv. This is still lower, however, than the ideal 58 mv which one would expect.

Holman (116) found more evidence to relate E_m and tension. She reported that raising Na_o to two or three times the normal level first increased tension and spike rate while reducing E_m . Later, as exposure was prolonged, the spikes disappeared although tension remained high and E_m low. These observations again argue for dissociation of spikes and tension, but later, Holman (118) took the position that spike frequency was an important factor in the development of tension and Axelsson (5) sustained this view.

The question of whether or not tension changes and electrical spikes are interdependent is of particular importance to our problem, since vascular tissue, so far as it has been studied, shows no spike activity whatever. Accordingly, tissues such as taenia coli are relevant only insofar as their tension may correlate with electrical activity other than that of a train of action potentials constituting the spike activity. Burnstock's recent study and argument is thus particularly important (24). He noted that smooth muscle of guinea pig taenia coli is relaxed by epinephrine and that this is associated with a rise in E_m and decrease of spike activity. The smooth muscle of the muscularis mucosa of the dog, by contrast, is contracted by epinephrine and in this case the epinephrine effect is associated with a fall in E_m and an increase in spike activity. It would therefore appear that at least for these types of visceral muscle both the membrane potential and the spike activity are correlated with tension. Under certain circumstances it is possible to dissociate the spike activity from the tension and the membrane potential alone then remains inversely correlated.

A similar situation arises in connection with studies of the uterus. The observation of Woodbury & McIntyre (212) that oxytocin, which contracts the pregnant uterus, reverses the membrane potentials of the single muscle cell is quite relevant for it again relates membrane potential to activity. On the other hand, the claim (43) that tension of the uterus strip is only correlated with spike activity suggests that this tissue is not analogous to vascular smooth muscle.

Electrical studies of vascular smooth muscle were almost nonexistent until very recently. Bozler (17) considered this type of muscle to be distinctive in being "multi-unit" unlike many other types which behave like single units. Recent detailed and elegant

studies by Burnstock & Prosser (25) and Prosser *et al.* (161) have placed this on a firmer footing. Vascular smooth muscle is here shown to consist of widely separated cells and its extracellular space calculated from electron microscopy is about 40 per cent of the total (see table 4). This contrasts strikingly with the other types of smooth muscle in which the extracellular space is estimated at less than 20 per cent. Vascular smooth muscle shows no conducted electrical activity and no spikes. Our theoretical discussion must reckon with these distinctive features.²

ROLE OF CALCIUM AND MAGNESIUM IN VASCULAR SMOOTH MUSCLE TENSION

Calcium

There is too little information concerning the detailed effects of calcium and magnesium on vascular tissue to permit any elaborate discussion. What little evidence we do have is fortunately consistent. The older literature has been reviewed by Evans (60). A much larger literature deals with the general direct involvement of calcium in the actomyosin system (51) and in the metabolic cycle of cells (141). We shall not develop this broad field of physiological chemistry, which would lead us far from our immediate subject, but we must note that calcium ions are evidently necessary for the contractile machinery to work.

The physiological implications of this have been demonstrated by Heilbrunn & Wiercinski (110). They showed that Ca in high dilution injected directly into the single skeletal muscle fiber caused an immediate and pronounced shortening. This effect is not shared by any other ion normally present in any quantity in muscle, but it is also produced by Ba. These authors, like others since (142), support the view that Ca links the ionic processes at the membrane to the contractile mechanism. This point obviously has as much importance for contraction and tonus in vascular as in any other muscle tissue.

In studies of intestinal segments there seems to be general agreement that the addition of Ca to the medium increases tone (189, 208). More important to our thesis is the demonstration that withdrawal of

² Recent successful impalement of single smooth muscle cells in turtle aorta and inferior vena cava segments has shown specialized types of action potential in association with tension changes. (Roddie, I. C. and S. Kirk. Transmembrane action potentials from smooth muscle in turtle arteries and veins. *Science* 134: 736, 1961.)

FIG. 10. Average effect of 10% CaCl_2 or 10% MgSO_4 infused into the brachial artery on dog forelimb vascular resistances. [Graph prepared from tabular data in Haddy (101).]

Ca from the medium causes a dissociation of the contractile mechanism from action potentials in the guinea pig taenia coli. From this, Axelsson & Bülbbring (6) have concluded that Ca is essential for the activation of the contractile mechanism by action potentials. Hurwitz *et al.* (121) have shown this in another equally direct way. They observed that prolonged exposure of the guinea pig ileum to a calcium-free environment divests the tissue of its ability to contract in the presence of an appropriate chemical stimulus. Further, the substitution of Mg for Ca in the medium accelerates the loss of contractility. Even so the membrane processes governing ionic exchanges still function so that a stimulus which no longer causes contraction will still cause K efflux.

Zsotér & Szabo (216) have reported that the feeding of a high calcium diet to rats for 10 to 15 weeks causes an increased sensitivity of the mesoappendix to the topical application of epinephrine. As we have discussed earlier, however, this type of result is difficult to interpret, since the variable (calcium feeding) is so remote from the target. Much more revealing is the observation of Haddy who showed that the infusion of hypertonic calcium salts caused constriction of all segments of the peripheral vascular bed of the dog forelimb under conditions of controlled flow (101). It will be recalled that hypertonic solutions in general produce vasodilatation so that the result with calcium is particularly striking. In a later study Overbeck & Haddy (156) reported that while the infusion of isotonic KCl produced peripheral vasodilatation, isotonic CaCl_2 caused vasoconstriction.

Woolley (213) has suggested that serotonin acts directly on the cell membrane to transfer calcium from the exterior to the interior of the cell. His evidence is quite incomplete, however, and a similar argument could be developed with equal reason to suggest that most if not all smooth muscle-contracting agents act through some similar mechanism involving calcium.

Magnesium

Haury (105) has clearly demonstrated that Mg relaxes bronchial smooth muscle and opposes the action of stimulating drugs. In well-controlled experiments in the dog and frog he found that small amounts of Mg given intravenously produced a blood pressure fall which was in large part due to peripheral vasodilatation (106). Schmid *et al.* (174) carried out a careful hemodynamic study in conscious dogs and also concluded that Mg salts produce peripheral vasodilatation as Hoff *et al.* (115) had earlier claimed. Stanbury (187) emphasized that the action of Mg is complex, since it produces changes in the autonomic nervous system and the heart as well as the peripheral vasculature. Zadina & Kriz (215) claimed that Mg had a direct relaxing effect on the isolated guinea pig intestine and depressed the response to stimulating agents.

Engbaek (59) reviewed the subject in 1952 and concluded that although it seemed reasonably certain that Mg ions acted to relax peripheral blood vessels this had not yet been shown to be a direct effect.

Pending any evidence to the contrary it seems reasonable to conclude, in summary, that Ca causes peripheral vasoconstriction and Mg relaxation. In general, these actions do not appear to be in any way specific to vascular smooth muscle. The special role of these bivalent metal ions in the chemistry of contractile protein may be involved and both ions, or at least Ca, may link membrane phenomena to the contractile mechanism.

ROLE OF H^+ AND OH^- IN VASCULAR SMOOTH MUSCLE TENSION

This subject is in a highly unsatisfactory state and permits no real conclusions other than that the pH of the medium is a most important variable, as we might have guessed. At this stage in the investigation of ions most workers are more concerned with maintaining

pH as an invariant than with noting and interpreting the effects of changes.

Schuler (177) measured the tension of mesenteric and phrenic artery rings while shifting pH to either side of normal. He found that tonus increased in both cases. Tobian *et al.* (198), using the spiral aorta strip of the rat, found that the contractile response to norepinephrine was maximal at relatively higher pH and minimal at lower. It seems to us that nowhere is the duration of immersion or exposure to the altered environment more important than in studies of the effect of H ions. Reference to table 2 will remind us of the extremely high mobility of H^+ and the ease with which it penetrates the membrane.

Rogers & Fenn (166) have shown that H^+ added to the medium exchanges rapidly with K^+ and Na^+ of cells. More recently, Saunders *et al.* (173) have also shown a partial replacement of K_i^+ with H_i^+ during dietary potassium depletion. At equilibrium, then, an original alteration in medium pH is replaced by an altered Na^+ and K^+ distribution. Duration of exposure must then be a critical variable. With this in mind, we can now examine the findings of workers using *in vivo* preparations. Technically, all the procedures to be quoted are beyond reproach as far as they go.

Burget & Visscher (23) showed a nice decrease in epinephrine response of the pithed cat proportionate to a stepwise fall in pH. This accords with Tobian *et al.* (198). Fleisch *et al.* (63) used good techniques to measure flow and pressure and found that a fall in pH of as little as 0.05 caused generalized vasodilatation.

More recent studies using the technique of controlled perfusion of a vascular bed are conflicting. Deal & Green (45), like Kester *et al.* (127) earlier, reported that solutions on the acid or alkaline side of physiological neutrality increased blood flow to limb muscles, indicating peripheral vascular relaxation. Skin vessels, however, showed a decrease in resistance as pH fell and an increase as pH rose. Fleishman *et al.* (64) showed that the picture is complicated by the fact that small vessel segments constitute independent resistances the magnitudes of which may actively vary in opposite directions. The net effects were dilatation of small vessels with an acute fall in pH and constriction with a rise in pH. Emanuel *et al.* (57) also reported that an acute rise in pH caused an increased peripheral vascular resistance through the renal vascular bed.

Clearly, we are in no position yet to draw any sort of general conclusions except that H ion effects are interwoven with those of Na^+ and K^+ .

FIG. 11. Average effects of pH change upon total and segmental vascular resistances in the nerve intact, nerve blocked, and nerve blocked phentolamine dog forelimb. [From Fleishman *et al.* (64).]

ROLE OF ANIONS IN VASCULAR SMOOTH MUSCLE TENSION

There is a great need for systematic study in this field. So far, although anions have been considered from time to time, they have been studied only to underline the effect of their associated cations. No approach to this problem will really make much sense, however, until an acceptable basic model for the role of cations in the regulation of vascular tension is presented. This model need not be the final one as long as it provides a good rational framework. We hope to present such an integrated view in the theoretical discussion to follow.

THEORETICAL INTERPRETATIONS

A rational theoretical interpretation of the available evidence is now quite possible and has been attempted

by several workers. Raab (162) has suggested that the amount of sodium in the smooth muscle cell determines its responsiveness to catecholamines which he considers important in the pathogenesis of hypertensive states. Tobian & Redleaf (200) suggest that the amount of both sodium and potassium increases in the vascular smooth muscle cell in chronic hypertension and, by osmotic attraction, causes cell swelling and water logging. Tobian has recently reviewed this position (193, 194). We have presented the theory that the sodium transfer systems, broadly defined, and expressed in the sodium gradient, determine vascular tone (78). Raab (163) has recently revised his position to incorporate the sodium gradient into his basic thesis of catecholamine sensitivity.

Insofar as the cell is concerned, neither the amount nor the concentration of Na or K enclosed by its membrane has any meaning apart from their relation to the external environment as the gradients Na_o/Na_i and K_o/K_i . An increase in Na_i , for example, attracts water into the cell until osmotic equilibrium is established only if Na_i has increased relative to Na_o . Again, an increase in K_o will redistribute itself so as to produce no osmotic effect at equilibrium if Na_o/Na_i is kept constant. Or again, insofar as membrane potentials are concerned, an increase in K_i hyperpolarizes the cell only if K_o/K_i is made steeper thereby.

We need not belabor the point implicit in the basic principles of the introduction to this chapter but only urge that a satisfactory theory must be based on concentration (or activity) gradients and not stress either cell or environment alone in isolation. It is equally apparent from the evidence presented that a satisfactory theory must embrace both sodium and potassium. We believe that the following theoretical interpretation will fit many of the presently known facts and will perhaps serve to stimulate further thought. It will be presented in the form of generalizations with some supporting evidence. The remainder of the evidence is contained in the body of this chapter.

1) Vascular smooth muscle tension is inversely proportional to the membrane potential, that is, to the sum of the equilibrium potentials of Na^+ and K^+ where, in the basal state, the permeability of the cell to K^+ considerably exceeds its permeability to Na^+ . Laborit & Huguenard (130) and Furchgott (87) have already expressed this view.

The simple shift of water from cells to environment which can be induced by increasing the external tonicity will increase both Na_i and K_i , hyperpolarize the membrane and relax the cell. This explains the

vasodilatation which consistently follows the infusion of hyperosmotic solutions. Sustained exposure to hyperosmotic solutions containing particles other than Na^+ will not only lower Na_o but induce a flow of K^+ from cells to medium so that at equilibrium the membrane potential will be reduced and tension increased. This may explain postnephrectomy hypertension (83).

2) Acute change in vascular smooth muscle tension is ordinarily accomplished by agents which alter the permeability of the membrane to Na^+ . An agent which increases the permeability to Na^+ will produce an immediate depolarization and increase in tension followed by a flow of sodium from environment to cells. Such a flow of sodium has been consistently induced *in vivo* by all vasoconstrictors.

If cell volume is to be maintained unchanged during this process, potassium must leave the cell as sodium enters. The expected increase in K_o does not occur with all vasoconstrictors. In this case we must assume that some cell swelling occurs. Pending further data we recognize that real changes in cell volume may also be involved in changes of tension in vascular smooth muscle (65, 195).

3) Sustained change in vascular smooth muscle tension may be accomplished by agents which adjust and sustain the membrane permeability to Na. The equilibrium state for a given permeability is manifest in the Na gradient. Since the entrance and exit mechanisms for sodium are not necessarily the same (see Goldman equation) the same result can be achieved by varying either influx or efflux rate. The sodium gradient falls, for example, if influx rate is increased or efflux hindered. If Na_i tends to accumulate in a sustained manner due to either of these changes the cell can, within reason, compensate by increasing its work of extrusion. Presumably the first effort of the cell to compensate will be reflected by an increase in the cell machinery involved in the work of such Na extrusion. This capacity must, however, be limited so that equilibrium will next be attained at a lower gradient, that is, Na_i increases until equilibrium is re-established. The resultant accumulation of Na_i must lead to the extrusion of K_i , a new and lower membrane potential and an increase of tension.

We have described the evidence that Na_i is actually increased in sustained hypertensive states. It is equally clear that chronic sodium-depleting procedures tend to re-establish the basic normal situation. There is also good evidence that mineralocorticoids regulate the permeability of cell membranes to sodium (33, 74, 123). A control system which allows a small trickle of sodium to enter the cell and then

regulates the ease with which it is extruded permits very fine control of the sodium gradient.

4) The role of cell volume remains to be assessed both in acute and chronic changes of vascular smooth muscle tension. This is self-evident. We are repeating this point at this time to emphasize the fact that this problem cannot be dealt with properly until such time as water movements can be accurately measured (65, 195).

SUMMARY

The detailed supporting evidence leading to our final theoretical interpretation is contained in the body

of this chapter. In order to underline our intention we have referred briefly to some essential evidence which cannot be easily explained in any alternate way. It is our opinion that most of the apparently complex material presented can be temporarily but usefully rationalized by reference to the theory presented. It is allied with general ionic theory as it applies to other contractile elements (113) modified to serve the special needs of this particular tissue.

We conclude that vascular smooth muscle tension depends on ionic distributions and mobilities across the cell membrane. The transmembrane equilibration of both sodium and potassium has been stressed as has the possibility of a direct link with calcium.

THE TERM "LIPID" enables us to assemble under one heading a number of organic substances which, although variable in chemical structure, are closely related in biological behavior. The physical and chemical processes by which a living organism operates are summarized by the term "metabolism."

Thus, lipid metabolism refers to the behavior in living organisms of fatty acids, their esters, certain hydrocarbons, phospholipids, and sterols. Recent technical advances permitting better separation, identification, and quantification of the various lipids have resulted in a vast store of new information about lipid metabolism. Much of this material still needs to be organized and evaluated in terms of its relevance to problems of human health.

"Atherosclerosis" (Gr. athero, mush) refers to a lesion of the arterial wall characterized, inter alia, by accumulation of lipid in the intima. The term was first suggested in 1904 by Marchand (144). Today atherosclerosis, by virtue of its deleterious effects on the various arteries of the heart, brain, and other important areas of the body, appears to be the major public health problem of Western man. Thus, by extension, lipid metabolism as it relates to the physiology and pathology of blood vessel walls has become a subject of vital importance.

The search for the etiology of atherosclerosis has included consideration of all elements in the classic epidemiologic triad—agent, host, and environment. Environmental factors have received special attention since evidence—epidemiologic, experimental, and clinical—has accumulated suggesting that dietary constituents and particularly dietary fats influence the development of atherosclerosis. Such evidence as applied to man necessarily has been indirect because of the inaccessibility of atherosclerotic lesions during life. It is now recognized that dietary constituents can profoundly influence lipid metabolism. The role

of diet-induced changes in serum lipids in the development of atherosclerosis has not been established. In man, atherogenesis appears to be a chronic process, requiring considerable time, perhaps years, to evolve. The disease can culminate in an acute obstructive event, frequently with disastrous consequences. At such a time a disturbance in the coagulability of the blood may occur resulting in the formation of an arterial thrombus. Thus, attempts have been made to correlate changes in serum lipids as influenced by diet with the development not only of atherosclerosis but also of a more acute change in coagulability of the blood.

The clinical sequelae of atherosclerosis, ischemia, and infarction of the heart, brain, and other tissues, have been carefully documented for years. Also, the gross pathologic processes, such as lumen encroachment, fibrosis, ulceration, calcification, and thrombosis, which underlie these clinical events have been understood by pathologists since the time of Virchow. Moreover, a reasonable explanation for the pathogenesis of the disease was advanced more than half a century ago and has not been disproved. Yet from the standpoint of etiology and intimate pathogenesis the basic nature of the disease remains obscure and debatable.

PATHOLOGY

The pathologic entity atherosclerosis must be distinguished from other blood vessel lesions, some of which have been previously lumped together with atherosclerosis under the generic designation, arteriosclerosis. Monckeberg's medial sclerosis differs pathologically, pathogenetically, and clinically from atherosclerosis. Various inflammatory lesions of blood vessel walls also can be sharply separated, although the generally held concept that thromboangiitis obliterans is an entity different from peripheral atherosclerosis recently has been questioned (209).

Another important consideration is that common textbook descriptions of atherosclerosis may in fact describe mostly complications or sequelae of an initial, clinically silent process that may start in infancy. Thus, lumen encroachment, fibrosis, calcification, ulceration, hemorrhage, and thrombosis are all late conditions.

What then is the initial lesion? What is the pathologic essence of the disease? The answer to these questions necessarily involves consideration of pathogenesis (to be discussed later) as well as descriptive

pathology. Fortunately, precise studies of early gross and microscopic lesions from human and experimental material are available (21, 55, 108, 109, 130, 162). The first gross lesion, often visible in infants, is the fatty streak, a linear yellow elevation usually found in the aorta. Microscopic examination of such a streak reveals underneath the heaped-up intima an accumulation of lipophages, cells which show a foamy, reticular cytoplasm with ordinary stains containing lipid solvents, but which are found, with appropriate fat stains, to be packed with lipid. Lipid is also found lying free between the lipophages. Whether the lipid which makes up the fatty streak is first intracellular or extracellular is as yet unknown. With larger lesions, lipid is also found below the internal elastic lamella in the media, but the smallest, earliest, grossly invisible lesions consist of a few foam cells lying directly under the endothelial surface of the intima. Thus, the lipid-containing foam cell is usually considered to be the earliest recognizable unit of the atherosclerotic process.

However, careful microscopic studies show other subtle anatomic changes (39, 126, 195) occurring *pari passu* with the appearance of lipid in the blood vessel wall. Elastic tissue stains reveal stretching and fragmentation of elastic fibers in the intima as an early feature. Other special stains show metachromatic changes in the ground substance of the arterial wall, and chemical studies have demonstrated mucopolysaccharide accumulations that occur along with, or possibly before, the appearance of visible lipid. An abundance of evidence, clinical and experimental, has shown that preceding damage to the arterial wall, toxic, infectious, chemical or physical, will accelerate and will influence the site of the atherosclerotic process. These findings have given rise to the theory that subtle, perhaps submicroscopic, alterations in the physicochemical state of the arterial wall may actually precede the more gross lipid accumulations.

PATHOGENESIS

Since the earliest pathologic lesions are only adumbrative, even with modern histochemical techniques, it follows that the intimate pathogenesis of the atherosclerotic lesion also remains obscure. It is understandable that nineteenth century pathologists considered the disease a degenerative one, an inevitable concomitant of the aging process and a simple result of wear and tear on the arterial wall. Even when atherosclerosis was separated from other arte-

rial lesions, it must still have appeared to pathologists of that era to be another phenomenon of aging, found along with cataracts, osteoarthritis and wrinkled skin, and occurring with increasing frequency with advancing years.

The pendulum did not swing until Ignatowski (110) in 1908 succeeded, by administering lipid-rich foods to rabbits, in producing arterial lesions similar to those occurring spontaneously in human subjects. A few years later Anitschkow (10) demonstrated convincingly that cholesterol in the diet was the atherogenic factor in experimental rabbit atherosclerosis. Since that time, a large body of evidence has led away from the degenerative theory. Some of these evidences are: the finding at autopsy of an occasional octogenarian virtually free of arterial disease; the contrary finding of fatal atherosclerosis in soldiers in their twenties; the relative freedom from the disease of premenopausal women; the increased incidence at autopsy of atheromatous lesions in patients with diseases involving lipid abnormalities such as diabetes, hypothyroidism, and other processes associated with hypercholesteremia and hyperlipidemia. Further information resulted from the epidemiologic finding of certain population groups relatively free of the disease at postmortem examination. Pathologists made further contributions to this change in concept by their studies in experimental animals; it is now recognized that, although man, certain other primates, birds, and swine are the only animals which seem regularly to acquire atherosclerosis spontaneously, there is a wide variety of species which can be caused to develop arterial lesions similar to those found in human material, providing only that appropriate experimental manipulations involving lipid metabolism are made.

All this pathologic evidence, along with a huge volume of clinical, epidemiologic, and biochemical studies, has led to the modern concept that atherosclerosis is potentially a preventable disease, a result of metabolic disorder rather than a degenerative process. This lipid concept of the pathogenesis of atherosclerosis can be stated in simple terms: man ingests an excess of lipid which overwhelms the mechanisms for its disposal; lipid then accumulates in the circulating blood and is deposited in the arterial wall.

How does this rather simple concept fit with the facts of the earliest recognizable pathologic lesion described above? At first glance, the fit seems perfect. An excess of lipoprotein material in the circulating blood filters through the endothelium of the arterial wall and is taken up there by tissue histiocytes to

form foam cells; the simple accumulation of these lipophages results in the gross arterial atheroma and sets off the chain of events leading to fibrosis, thrombosis, and the rest. Yet there are a number of questions which cast doubt on this simple hypothesis.

First, if the mechanism is merely one of filtration through the endothelium to the arterial intima, why are the anatomically similar veins not more susceptible to the atheromatous process? That intraluminal pressure plays some role is shown by the increased incidence of atherosclerosis in hypertensive patients, the occurrence of pulmonary artery atherosclerosis in individuals with pulmonary hypertension, and the finding of phlebosclerosis adjacent to arteriovenous fistulas.

Another disturbing question concerns the fact that the lipid deposit is not a universal arterial finding, coating the intima of the entire arterial tree, but rather a spotty, localized one, involving certain segments of certain arteries. A number of possible explanations for this finding have been offered. One argument is that localized changes in filtration pressure, occasioned by intraluminal physical forces such as whirlpool and eddy formation, determine the site at which lipid is deposited; the frequent occurrence of atheromatous lesions at bifurcations, branches and coarctations favors this theory (175). Another proposal relates the clinical predilection for thrombosis in atherosclerosis to its pathogenesis; the earliest lesion, by this concept, is a chance fibrin deposit on the endothelial surface, the spotty lipid lesion occurring secondarily to fibrin deposition (56). Another explanation depends on the clinical and experimental evidence that preceding arterial wall damage, physical, chemical, mechanical, or bacterial, will foster premature and extensive lipid deposits; by this theory, occult damage to the elastic tissue or ground substance (or both) of the arterial wall, from degenerative or extraneous cause, serves as the spotty focus for lipid deposit. Still another theory explains the spottiness on the basis of localized differences in various areas of the arterial wall, in the mechanisms for removal of lipid, either metabolic (enzyme overload), scavenging (number of histiocytes present) or anatomic (number of lymph channels present). Yet another hypothesis explains localization by denying filtration from the lumen; according to this concept, atheromatous lesions are preceded by a localized overproduction in the arterial wall of the lipids which make up the lesion (105). Sensitive radioactive tracer studies have indeed shown that arterial tissue can synthesize lipids, but recent reports (214) have indi-

cated that if any atheroma lipid comes from local synthesis, it is probably only the phospholipid component.

One other major question relating to the intimate pathogenesis of the atherosclerotic lesion remains unanswered: What are the mechanisms for incorporation of lipid into cells to form lipophages? In each of the hypotheses mentioned above for the pathologic background of the early lesion, the common hallmark, whether primary or secondary in time and in importance, is the lipophage or foam cell (156), the very name of which suggests incorporation of lipid (fig. 1). The knowledge of the exact derivation of the foam cell is fundamental to a better understanding of atherogenesis.

Is anabolic activity necessary for the accumulation of lipid in the cellular cytoplasm (as opposed to an engulfing mechanism)? One clue may be that the lipophage differs from the lipocyte, or adipose-tissue cell, by the former's higher content of protein and lipids other than neutral fat. Current attempts to study this problem by *in vitro* tissue culture techniques (180) may help to answer this and other

important questions about the role of the lipophage in atherogenesis.

Do lipophages form simply because there is lipid material available to be engulfed or phagocytized? In favor of this concept is the observation that lipophages are not peculiar to the atherosclerotic lesion; they are found as part of the detritus in hemorrhage into the various tissues; they are found as apparent scavengers in lipoid pneumonia; they occur in degenerating tumors; they are found experimentally after the subcutaneous injection of cholesterol suspensions; and they are found in the lipoidoses (Niemann-Pick, etc.) in massive accumulations involving the reticuloendothelial system. In most, if not all, of these situations, it is reasonable to assume that a scavenging attempt to rid the tissue of a local excess of lipid is involved.

Yet, in the atheromatous lesion, there appears to be an additional element—one of accumulation. A single minute atheroma, invisible to the naked eye, is made up of a tremendous number of lipophages, packed together in the subintima in such volume as to displace adjacent normal tissue and to project into

FIG. 1. Photomicrograph of a foam cell protruding from the subendothelial space of a rat aorta. $\times 8,400$. (Courtesy of Robert M. O'Neal, Baylor University.)

the lumen. What the stimulus is to cause this proliferative (or accumulative) element is unknown; the answer to this question is vital to a proper understanding of the intimate pathogenesis of atherosclerosis.

In summary, the major facts concerning the pathology of atherosclerosis, particularly its grosser aspects and its sequelae, are well documented. Debate still exists, however, concerning the more subtle, microscopic manifestations of the early atheroma, particularly in regard to the primacy of lipid deposition.

After more than fifty years, the lipid theory, despite some unanswered questions, seems to be standing the test of time. It will not become a universally accepted theory until certain difficulties are overcome. The spotty localization of arterial lesions, the mechanism of incorporation of lipid into tissue cells, and the stimulus to cellular accumulation in atheromatous lesions all are unsolved problems.

METABOLIC CONSEQUENCES OF INGESTION OF FOOD

Assimilation of foodstuffs is a condition of animal life. Yet food is never deposited unchanged. For absorption to take place, foodstuffs must be split, and far-reaching chemical transformations follow the absorption of digested food. The transformed food may be oxidized for the immediate production of energy or stored for short or long periods, depending on the needs of the body. With the exception of certain essential nutrients, the body is able to synthesize, interconvert, store, and mobilize its constituents.

When an individual ingests an assimilable carbohydrate, practically all of it is absorbed from the digestive tract and eventually reaches the liver as hexose. Part of the hexose is converted to liver glycogen; part is released into the circulation to be distributed to extrahepatic tissues; part enters muscle, where it is either burned or stored as glycogen. Once glucose enters muscle, becoming phosphorylated, it can no longer leave as such. One of its breakdown products, lactic acid, can diffuse out of muscle cells and re-enter the circulation. The adipose cells transform glucose into fatty acids, which are esterified with α -glycerophosphate to form triglyceride and are stored in this form. Glucose products, by a process of transamination, can be converted into amino acids.

Protein must be hydrolyzed into amino acids prior to absorption. Subsequently the amino acids can be

rebuilt by the body into new protein. Some of the amino acids can be converted to carbohydrate and thence to fat. Their carbon skeletons also are available for oxidation.

Following digestion, fatty acids passing through the intestinal mucosa are incorporated into very low-density lipoproteins (chylomicrons); these "molecules" are distributed in the systemic circulation to be disposed of by hydrolysis, oxidation, interconversion (but not into carbohydrate), or storage in various tissues.

Thus, carbohydrate and protein can be converted to and stored in the body as fat.

Soon after a conventional meal has been consumed, changes in concentration of glucose, amino acids, and fat (chylomicrons) occur in the blood. These "primary" changes induce "secondary" changes in the metabolic state. Ingestion of fat is followed by a postprandial lipemia, which may last for many hours. Thus, to evaluate the serum lipids properly, it is important to obtain blood samples from subjects who are in the postabsorptive state.

DIET

The average American diet, according to a summary of the 1955 Household Food Consumption Survey conducted by the United States Department of Agriculture (65), derives 44 per cent of its caloric content from fat, 13 per cent from protein, and 43 per cent from carbohydrate. The survey made no deductions for food discarded. The breakdown of calories derived from fat was: 18.3 per cent from saturated fatty acids, 18.6 per cent from oleic acid, and 4.5 per cent from linoleic acid. As expected from such an extensive survey, there were some regional differences in types and quantities of food consumed.

Knowledge of the chemical composition of natural fats remains incomplete, although great strides forward are being made. It is generally agreed that most natural fats, whether animal or vegetable, contain about 98 to 99 per cent triglycerides. The remaining 1 or 2 per cent includes diglycerides, monoglycerides, free fatty acids, phospholipids, and unsaponifiable sterols. Fatty acids comprise over 90 per cent of the triglycerides, with the remainder being glycerol. The naturally occurring triglycerides are mixtures varying widely in their patterns of fatty acids. The complexity of such glycerides is underlined

by the observation that at least 64 different fatty acids have been identified in butter fat (101).

In general, the degree of unsaturation of the fat depends upon the source of the fat. Fats of aquatic origin contain a wide range of unsaturated C_{16} , C_{18} , C_{20} , and C_{22} acids. Fats from land animals contain 25 to 30 per cent C_{16} , the remainder being mostly of the C_{18} series (102). The so-called essential fatty acids (mainly linoleic) apparently cannot be synthesized by animals, and must be obtained from the diet. The depot fat of certain animals, such as the pig, can be varied markedly in its content of linoleic acid, depending on the feed (60). Similarly, the adipose tissue fatty acids of man eventually reflect the dietary fatty acid pattern. This is true with respect to linoleic acid (103); but the medium chain fatty acids (C_{12} and below) have not been identified in the fat depots. Fats of vegetable origin vary tremendously in their pattern of fatty acids, as well as in their degree of unsaturation. For instance, coconut oil contains only a small quantity of linoleic acid, while safflower oil may contain 70 per cent or more. Dietary fats should not be described merely as "animal or vegetable," "saturated or unsaturated," but the actual composition in terms of fatty acids should be identified. Thus, when the effects of dietary fats on lipid metabolism are being evaluated, the specific fatty acids involved, their chain length, isomeric configuration, degree of unsaturation, and relative proportion in the diet must be considered.

Dietary phospholipids are found as complex mixtures in organ fats and certain raw vegetable fats, rather than in depot fats. Egg yolk is a rich source of phospholipid. As indicated by their name the phospholipids are a group of phosphorus-containing lipids; in addition, they contain a nitrogenous base. The lecithins, in which the base is choline, and the cephalins, in which the base is ethanolamine or serine, are classified as mono-amino-phosphatides. The component fatty acids are usually both saturated and unsaturated. The inositol phospholipid contains ethanolamine and tartaric acid. It is found in soybean phospholipids and in brain tissue. Other phospholipids include sphingomyelin, which is a diamino-phosphatide containing choline and sphingosine. Plasmalogens contain higher fatty aldehydes and ethanolamine (69). The complexity of dietary phospholipids is illustrated by their occurrence in egg yolk: 72.8 mols per cent phosphatidyl choline; 14.8 per cent phosphatidyl ethanolamine; 2.1 per cent lysophosphatidyl ethanolamine; 5.8 per cent sphingomyelin; 0.9 per cent plasmalogen; 0.6 per cent inositol

phospholipid; and 0.2 per cent phosphatidyl amine acids (169). One egg contains about 2 g of phospholipid.

The unsaponifiable fraction of food fats consists of sterols, including cholesterol (absent from vegetable fats), long-chain aliphatic alcohols, glycerol ethers, pigments, etc. Finally the fat-soluble vitamins, A, D, E, and K, may be found in this fraction.

FAT DIGESTION AND ABSORPTION

Generally speaking, lipids are not readily miscible in water. To be able to absorb, transport, and utilize fatty acids and other lipids, man has had to evolve rather elaborate mechanisms for making these water-immiscible or hydrophobic materials compatible with a system whose basic medium is water. The mechanisms used to deal with the water-insoluble lipids as they enter the body include hydrolysis, emulsification, chemical combinations with substances containing hydrophilic groups, and complex formation with substances conferring greater water miscibility and dispersibility, such as bile acids and proteins.

The mechanisms of digestion and absorption of dietary fat have been subjects of controversy for many decades. An early theory was proposed by Pflüger (161) who described dietary fats as being emulsified by bile salts in the small intestine. The triglycerides were then completely hydrolyzed by pancreatic lipase to fatty acids and soaps. Being water-soluble, these products were readily absorbed. However, it soon became apparent that intestinal pH is too low for fatty acids to exist as soaps. It also became apparent that the absorbed fat in lymph is mainly in triglyceride form. Thus, glyceride resynthesis by the intestinal mucosa was postulated. The modern concepts of fat absorption arise from Frazer's work (67, 68). It is now believed that hydrolysis of dietary glycerides need not be complete in order for absorption to occur.

Frazer's original "partition theory" (66) postulated that fatty acids passed directly into the portal circulation while the partial and unchanged triglycerides were somehow transported across the mucosa into lymph as chylomicrons. This theory has failed to survive in its original form as a result of more recent work (16, 145) including Frazer's own (70). Portal venous transport of fat is now known to occur only with fatty acids of less than ten carbons, which comprise less than 5 per cent of dietary fats.

The digestion and absorption of long-chain fats remain a subject of controversy. Frazer (70) has

cally normal men (38). In obese individuals the amount of body fat may reach 33 to 40 per cent of body weight.

During the past twenty years there has been an increasing awareness that adipose tissue is a dynamic organ capable of responding to a variety of stimuli. The experiments of Schoenheimer (184) and others have shown that depot fat has a definite turnover. Its half-life in the rat has been estimated to be 6 to 8 days. In man, turnover of depot fat is much slower, with a half-life of many months, in the presence of adequate caloric intake. When the availability of carbohydrate is reduced, depot fat cells can quickly mobilize free fatty acids which are then bound to albumin and carried in the blood to muscle, liver, and other tissues (52, 84).

The relationship between the availability of carbohydrate and the rate at which fatty acids are mobilized from depot fat is important. Breakdown of glucose through the Embden-Myerhof pathway and the hexosephosphate shunt may provide certain cofactors necessary for fatty acid synthesis (lipogenesis). Insulin promotes entry of glucose into the cell and thereby provides a stimulus for further metabolism of this hexose. Fatty acid synthesis appears to be somehow dependent on the rate of glycolysis. In diabetes mellitus glycolysis is depressed because of insulin lack; in addition, the rate of fatty acid synthesis is greatly suppressed. At the same time, the rate of hydrolysis of depot fat increases, and the resultant fatty acids are carried into the circulation as free fatty acids. For example, in uncontrolled diabetes, enormous amounts of fat can be mobilized, leading to fatty liver, hypertriglyceridemia, and hyperketonemia. Administration of insulin corrects the situation in a manner that has not been elucidated (203), but probably relates to the ability of insulin to reduce the rate of fatty acid mobilization from adipose tissue.

Hormonal Influences on Adipose Tissue

In addition to insulin, several other hormones have been found to influence lipid mobilization. It is emphasized that hormones do not initiate events within cells, but merely regulate the rate at which some of these events occur. Early studies (148) indicated that when large doses of posterior pituitary extract were injected into rats or rabbits there resulted an accumulation of fat in the liver. Similarly, an increase in liver fat and a decrease of carcass fat of the rat were found following the injection of anterior pituitary extract (19). There have been recent reports

that a posterior pituitary component, a relatively small polypeptide, has a potent mobilizing effect on omental and mesenteric fat in animals and man (185, 213). As yet there have been no reports on the influence of this posterior pituitary material on mobilization of free fatty acids (95). In contrast, it was found (177) that the injection into rabbits of crude extracts of whole or anterior pituitary gland of hogs, sheep, cattle, or man induced visible lipemia which was considerably greater than that induced by recognized anterior pituitary hormones. Thus it was suggested that the lipemia-producing principle might be an independent hormone, or that the lipemia was the result of synergistic action of known hormones, although the lipemia-producing anterior pituitary component apparently contains negligible or undetectable amounts of eight known pituitary hormones (178). Also, following injection of this material into rabbits, there was a rapid and enormous (tenfold) increase in free fatty acid levels. This was followed within 12 hours by a twofold to fivefold increase in serum total lipid concentration, including significant increases in the serum levels of triglycerides, cholesterol, and phospholipid. It is difficult to ascertain from these studies whether or not the lipemia that was produced was mediated through another gland, since the recipient animals were neither hypophysectomized nor adrenalectomized. The authors have explained their results by postulating that the active principle mobilizes free fatty acids from depot fat. The increase in triglyceride, cholesterol, and phospholipid in serum is believed due to increased rate of formation of these substances in the liver, in response to increased hepatic uptake of free fatty acids.

The possibility that there may be two new factors capable of mobilizing depot fat, one from the anterior and one from the posterior pituitary, deserves further exploration and confirmation by other investigators.

Of the known pituitary hormones, growth hormone has been shown to possess free fatty acid-mobilizing properties in the intact organism (168). Growth hormone action on depot fat (and other sites) appears to depend upon the phylogenetic relationship of the recipient animal to the donor source. For example, beef growth hormone mobilizes fat in cattle and in the rat but not in monkeys or human subjects. Knobil (125) has shown that the administration of growth hormone stimulates, while hypophysectomy inhibits, free fatty acid release from the epididymal fat body of rats. The manner in which growth hormone promotes free fatty acid release has not been fully elucidated.

Adrenocorticotrophic hormone (ACTH) has been

found to be very active in inducing free fatty acid release from adipose tissue in vitro (43, 61). However, such an effect is not readily demonstrated in vivo. The reason for this discrepancy is not clear, although a difference in species response to ACTH with respect to free fatty acid release has been offered as a possible explanation (61).

The role of thyroid in the metabolism of depot fat also is under study. The lipolytic response of adipose tissue from thyroidectomized animals (which had been suppressed) was made normal by restoration of the euthyroid state, while hyperthyroidism accentuated such a response (170). Moreover, it has been shown that the treatment of hypothyroid patients with thyroid restored to normal their free fatty acid response to growth hormone (167). Thus the thyroid appears to play a permissive role in fat mobilization, potentiating the action of certain lipolytic agents.

The autonomic nervous system was long suspected of playing an important part in the metabolism of depot fat (24, 207). Early observations on the autonomic innervation of adipose tissue have received support from more recent studies on the action of epinephrine and norepinephrine on depot fat. Subcutaneous administration or intravenous infusion of epinephrine and norepinephrine induced significant elevations of free fatty acids in the plasma of intact animals and human subjects (52, 80, 84). Moreover, adipose tissue in vitro has been found to be exquisitely sensitive to epinephrine and norepinephrine in terms of free fatty acid release (27, 61, 137, 210). It has been shown that adipose tissue liberates glycerol in response to epinephrine and norepinephrine (61, 137) suggesting that the mode of action of these hormones on adipose tissue involves hydrolysis of triglyceride. An epinephrine-sensitive lipolytic system has been reported in adipose tissue (172). The influence on depot fat of chronic administration of epinephrine and norepinephrine, as well as other sympathomimetic agents, remains unknown.

The various factors influencing lipogenesis and mobilization of fat from adipose tissue are summarized in figure 3.

In view of the importance of the subject of lipid mobilization and lipogenesis in the scheme of knowledge about metabolism, it is surprising that investigation in this area has lagged until recently. Conceivably, as knowledge of the subject increases, the physician will be the beneficiary of valuable adjuncts in the treatment of lipid disorders. Thus, adipose tissue, once thought to be a relatively inert storehouse of dense calories, has been found capable of partaking

FIG. 3. A scheme of lipogenesis and lipolysis in the adipose cell. Free fatty acid release is promoted by: glucose lack, starvation, insulin lack, epinephrine, glucagon (in vitro), norepinephrine, growth hormone, ACTH (in vitro), thyroid hormone (? permissive), and certain extracts from anterior and posterior pituitary glands.

actively and rapidly in a number of metabolic processes and of responding to a variety of humoral and autonomic stimuli.

THE SERUM LIPIDS

The serum lipids can be broadly classified under two major headings: the lipoproteins and the free (or nonesterified) fatty acids (FFA or NEFA). The lipoproteins represent a whole spectrum of lipid molecules containing varying proportions of phospholipid, cholesterol (free and esterified), protein (polypeptide), glyceride, and water. The lipoproteins have been classified according to their behavior in the ultracentrifuge, by their migratory behavior during electrophoresis, by their principal N-terminal amino acid residue, by their solubility characteristics, and other ways (155, 194). The density of the lipoprotein molecule is largely a function of the proportion of lipid contained within it; hence, the more "obese" the molecule, the lower its density.

The lipoprotein species with the lowest density are the chylomicrons; the remaining species can be further divided according to their electrophoretic migration with alpha globulins and beta globulins into two groups, the lower density (beta) lipoproteins and the higher density (alpha) lipoproteins.

The free fatty acids are present in a relatively low concentration in plasma under basal conditions (approximately 0.2 to 12.0 meq/liter). However, they appear to have a rapid turnover rate. They travel in the circulation bound to albumin and per-

haps to other substances, and consist principally of fatty acids common in the diet, such as palmitate, stearate, oleate, and linoleate.

Chylomicrons

The elaboration of chylomicrons by the intestinal mucosa has been discussed. These small particles enter the systemic circulation via the intestinal lacteals and thoracic duct. The chylomicrons in the blood are responsible for the visible lipemia that occurs after a meal containing an appreciable quantity of fat. Similar (but not identical) particles manufactured by the liver seem to be responsible for the lactescence that occurs in uncontrolled diabetes, nephrosis, and carbohydrate-induced hyperlipemia. From an analytical standpoint, chylomicrons have been characterized as the material floating at the top of a tube when chyle or serum is layered under saline of density 1.006 and centrifuged for a few minutes at high speed. Varying speeds and time of centrifugation have been suggested, but it is assumed that the lower the speed and the shorter the time of centrifugation, the purer will be the chylomicron fraction (71). One procedure (135) uses 9500 *g* for 10 min. The actual density of chylomicrons is 0.94 *g* per ml.

When chylomicrons are released into the systemic circulation from the thoracic duct, they are removed with considerable rapidity by the liver and extrahepatic tissues. The mechanisms of removal are incompletely understood; however, these small fat particles apparently are not hydrolyzed to any appreciable degree in the circulating blood, although evidence for intravascular hydrolysis has been presented (62). To some extent, fatty acids may be split away from chylomicron triglyceride through the intervention of the enzyme, lipoprotein lipase, but this action probably occurs primarily at endothelial surfaces and other cell membranes and not in the main stream of the circulation (71).

More important mechanisms for chylomicron removal may include direct diffusion into cells through "pores," and phagocytosis by appropriate cells. When the subject is in the postabsorptive state and carbohydrate no longer is readily available, a larger proportion of the chylomicrons from a test meal of fat will be removed by liver and muscle; when excess carbohydrate is available (that is, during hyperglycemia), the chylomicrons are shunted to a greater extent to the fat depots. The clearing of visible lipemia after ingestion of fat may be inhibited if a

previous fat load has been given and has recently been cleared. Although a large amount of chylomicron fatty acid is directly oxidized, some of it may recirculate in the form of free fatty acid. Thus, a variable rise in free fatty acids occurs in blood during the course of an alimentary lipemia (71, 72).

The Lipoproteins

In normal human plasma, the lipoproteins constitute approximately 12 to 15 per cent of the total protein (155). A fundamental difference between the lipoproteins and the remainder of the plasma proteins is that the former are lipid-laden molecules with relatively low density. The plasma lipoproteins exhibit densities from 0.9 to 1.2, in contrast to densities of 1.26 to 1.38 for most other proteins. Thus, the ultracentrifuge has become a useful tool in the separation of the plasma proteins and lipoproteins, utilizing measurement of the differing sedimentation rates of molecules in solvent systems of known density. Gofman and his associates (78, 79, 135) have used a sodium chloride solution with a density of 1.063 to differentiate lipoproteins. These workers have also introduced the " S_f " nomenclature which is used to describe the rates of flotation (varying S_f values) of the various lipoproteins in sodium chloride of density of 1.063. Such rates of flotation are measured in Svedberg units (S_f unit, 10^{-13} cm *g* sec⁻¹ dyne⁻¹). Apparently the S_f value is dependent on the density, shape and size of the lipoprotein molecules (155).

A plethora of terminology relating to the lipoproteins has evolved depending on methods of isolation and identification (71, 78, 134). The subdivisions sometimes have been rather arbitrary, yet certain correlations have been made as, for example, between the ultracentrifugal and electrophoretic behavior of the lipoproteins. It has been demonstrated that there are two major groups of lipoproteins (three if chylomicrons are included) in human plasma: 1) high-density lipoproteins (density > 1.063), or α -lipoprotein by virtue of their electrophoretic mobility; 2) low-density (< 1.063) or β -lipoproteins. The latter (< 1.063) include the classes S_f 0-400 of Gofman (78). The chylomicrons (density 0.94; see above) have virtually no electrophoretic mobility, but exhibit no definite line of demarcation from the S_f 400 low-density lipoproteins, and their S_f value may reach 40,000. Studies of the protein moiety of the lipoproteins have yielded information which may further help characterize the ultracentrifugally separated fractions. Information is available (71)

with respect to molecular weight, end group analyses for specific peptide chains, amount and type of N— and C— terminal amino acids, etc. Such information remains preliminary in nature. A schematic conception of the various human plasma lipoproteins is shown in figure 4.

The lipid moieties of the various lipoproteins (other than chylomicrons) may comprise from 40 to (perhaps) 90 per cent of the molecule. These include a small amount of free fatty acids, and virtually all the esterified fatty acids as esters of glycerol or more complex alcohols, and cholesterol. Free cholesterol also is present. Normal human postabsorptive plasma contains approximately 400 mg per 100 ml esterified fatty acids. Approximately 70 per cent of such fatty acids exist as triglycerides and phospholipids, and the remainder as cholesterol esters (141). Small amounts of esterified fatty acids may be found as diglycerides and monoglycerides, cerebroside and acetals (71).

Despite the high proportion of lipid in the lipoproteins, they have the chemical and physical characteristics of protein molecules. Such behavior suggests that the protein moiety is on the surface of the molecule. For instance, it has been estimated (35) that a chylomicron of $0.5\ \mu$ may be covered completely by protein, assuming the protein to be all at the surface and constituting 1.5 per cent of chylomicron.

micron. However, it has been pointed out that in the larger β -lipoprotein there is only enough protein to cover about half the surface, assuming a thickness of one peptide chain. On the basis of titration data, Oncley *et al.* (154) have postulated a kind of mosaic surface comprising both peptide and phospholipids, the latter being oriented with their charged groups at the surface.

Under ordinary circumstances, the alpha lipoproteins, or high-density lipoproteins, probably do not transport triglyceride for oxidative purposes. Recent studies (176) with labeled amino acids have suggested that the plasma does not contribute a major portion of the protein found in either the chylomicrons or the high-density lipoproteins in thoracic lymph. Since the cells of the intestinal mucosa incorporate amino acids into proteins having the same electrophoretic mobility as chylomicron protein, it was theorized that the intestine may be the source of the protein of both the high-density (alpha) lipoproteins and the chylomicrons.

The alpha lipoproteins contain approximately 40 per cent lipid; are not remarkably influenced by diet or fasting and do not increase with age. In terms of blood level, they are relatively stable.

In contrast, the low-density (beta) lipoproteins, which contain 75 per cent or more lipid, are labile; they are affected by diet, fasting, age and gonadal

FIG. 4. Schematic conception of human lipoproteins. Cross-hatching or stippling represents polypeptide portions of the molecules. [From Frederickson & Gordon (71).]

hormones, and by a variety of other influences. In fasting states and when carbohydrate utilization is decreased, serum levels of these low-density lipoproteins tend to increase; however, appreciable rises in concentration of such molecules occur only after the fast has been sustained. Ordinarily, such a rise in circulating beta lipoproteins is preceded by an increase in plasma levels of free fatty acids.

There is some evidence that lipoprotein interconversions occur and that, as fatty acids are split off a low-density lipoprotein molecule, its density progressively increases. When heparin is administered, thereby stimulating lipoprotein lipase activity, the interconversion process is greatly accelerated (62).

Free Fatty Acids

The free fatty acids comprise less than 10 per cent of the total fatty acids found in plasma. Strictly speaking, these acids are not "free" since they circulate bound to albumin. Each molecule of albumin can bind two or more molecules of long-chain fatty acid (83).

The free fatty acids represent one important form in which fatty acids are transported from sites of storage (fat depots) to working cells (see above). They do not appear to derive directly from dietary fat. However, dietary fatty acids with chain lengths of C_{10} or less, a very small fraction of fat in the diet, may enter the circulation from the gut via the portal vein in the "free" form (28), although their esterification with glycerol by the intestinal mucosa may also occur (160). Actually, the level of circulating free fatty acids falls after a normal meal. On the other hand, during the course of clearing of alimentary lipemia, a variable fraction of the circulating free fatty acids may originate from chylomicron triglyceride (71).

Studies of the distribution of C^{14} -labeled palmitate (bound to albumin) in rats 15 min after intravenous injection have disclosed a general uptake of the label by various organs and by muscle. Liver lipids were particularly active, whereas adipose tissue had no detectable activity (53). If such experiments can be considered representative of the behavior of free fatty acids under normal circumstances, it would seem that the plasma free fatty acids are removed rapidly in various parts of the body, with subsequent oxidation or esterification, depending upon metabolic circumstances.

There is growing evidence that the free fatty acids constitute an important source of the body's energy in the fasting state; they are released in increasing

amounts by the adipose tissue and used very rapidly at times when carbohydrate utilization is diminished (52). Experimentally induced elevation of the blood sugar or of blood amino acids (94) results in a reciprocal drop in plasma levels of free fatty acids.

Calculations suggest that the circulating free fatty acids probably do not supply more than 50 per cent of the energy in the fasting state; hence, it may be suspected that another important source of energy during fasting is esterified fatty acid (71). Isotope studies have shown that the fatty acid turnover is much more rapid in triglyceride than in cholesteryl ester and phospholipid (13). Thus, the serum glycerides may well function as a major vehicle for transport of esterified fatty acid to sites of utilization.

Ordinarily, in the postabsorptive state, triglyceride moieties travel in the blood as parts of low-density lipoprotein molecules that are neither large nor numerous enough to affect the gross clarity of the serum. However, under conditions of metabolic stress, and in certain disorders, lipoproteins of very low density appear in the circulation in quantities sufficient to render the plasma lactescent. It is unlikely that such particles can be released directly from the fat depots and evidence is accumulating that they originate from the liver.

Role of the Liver

The liver plays a major role in the synthesis and disposal of lipids and lipoproteins. With the exception of the chylomicrons, it appears that lipoprotein manufacture takes place principally, if not exclusively, in the liver. The various factors that influence hepatic synthesis of lipoproteins are not well understood. The process whereby the intestinal mucosa handles dietary fats and transforms them into chylomicrons, some of which are removed by the liver, has been discussed already. Adipose tissue releases fat in the form of free fatty acids "bound" to albumin. These acids also are extracted in appreciable quantities by the liver. Carbohydrate and protein can be converted into fat by the liver. In short, the liver is presented with lipid from several sources, and can itself synthesize lipid, including cholesterol and phospholipid. Thus, the lipoproteins that the liver manufactures and sends out to the circulation are made from a variety of building blocks and are subject to a variety of metabolic influences including diet and hormones. These concepts concerning the origin of serum lipids are shown in schematic form in figure 5. In the case of certain lipids, such as cholesterol, the liver is the

FIG. 5. Origins of serum lipids.
[From Van Itallie & Felch (201).]

major organ of catabolism and excretion. Elaborate mechanisms exist in the liver for disposal of the steroid nucleus of cholesterol, since the body lacks the mechanisms capable of opening the rings of phenanthrene-like structure.

Cholesterol Disposal

As mentioned above, cholesterol represents a special disposal problem. Fatty acids and glycerol are readily metabolized, and phospholipids are freely miscible with water and can be degraded rapidly. On the other hand, although the isopropyl side chain of the cholesterol molecule can be oxidized, with formation of bile acids and certain hormones, the steroid nucleus itself is not degraded.

It is now established that bile acids constitute the major catabolic end products of cholesterol metabolism in man and in a variety of animal species (17, 18, 97). In man, conversion of cholesterol to bile acids occurs in the liver. The biochemical details of this conversion have not been completely worked out. It is generally agreed that in man two "primary" bile acids (hydroxycholanic acids) result from catabolism of cholesterol in the liver: cholic acid and chenodeoxycholic acid (fig. 6). Five important biochemical changes must occur in the cholesterol molecule, and not necessarily in the order listed: *a*) isomerization of the 3 β -OH into 3 α -OH; *b*) saturation of the 5:6

double bond; *c*) hydroxylation at the 7 position (chenodeoxycholic) *d*) hydroxylation at both 7 and 12 positions (cholic); and *e*) oxidation of the terminal isopropyl group resulting in a C-24 acid (cholanic). The resultant bile acids are secreted into the extra-hepatic biliary system as micellar conjugated compounds with either glycine or taurine. In man the conjugation process favors glycine by a factor of three (18). In the intestine the bile acids may undergo further chemical transformations attributed to intestinal microorganisms, giving rise to "secondary" bile acids. For example, cholic acid will lose its 7 α -OH group to yield deoxycholic (3 α , 12 α -hydroxycholanic) acid, and in a similar manner chenodeoxycholic acid will yield lithocholic (3 α -hydroxycholanic) acid. Thus the 7 α -dehydroxylation is a bacterial function. A number of additional bacterial metabolites of hepatic bile acids have been found in human feces, although their importance quantitatively has not been determined (111). In addition, the bacteria split the conjugated compounds into glycine, taurine and their corresponding bile acids. Most of the bile acids are reabsorbed from the intestine into the liver via the portal vein. A small portion is excreted in the stool in unconjugated form. In the normal gastrointestinal tract virtually no cholic acid can be identified in the feces.

It has been estimated that the normal adult individual synthesizes about 1.2 g of cholesterol per day. Approximately 70 per cent of this amount (0.8 g) is

FIG. 6. Formation of "primary" and "secondary" bile acids in man. (From Van Itallie & Hashim, *M. Clin. North America*. In press.)

excreted as bile acids, and a portion of the remainder is excreted in the feces as cholesterol, coprostanol, cholestanol, and other nonacidic sterols. The newly formed bile acids are excreted into the small intestine and participate in an enterohepatic cycle through which 20 to 30 g of bile acids circulate per day (fig. 7). The net loss of bile acids in the feces normally corresponds to the amount converted from cholesterol in the liver.

That bile acids are the major catabolic products of cholesterol has been suspected for about a century. However, this fact was clearly established in 1943 by Bloch *et al.* (26) who demonstrated that, when cholesterol labeled with deuterium was administered to dogs, a minimum of two-thirds of the label appeared in the excreted bile acids. These observations have now been amply confirmed by studies involving use of C¹⁴-labeled cholesterol, notably by Siperstein *et al.* (191, 192), Bergström *et al.* (17, 18), and others.

The behavior of the enterohepatic cycle of bile acids profoundly affects the rate of cholesterol conversion to bile acids. This rate in turn appears to influence plasma cholesterol concentration. Rats with

FIG. 7. Enterohepatic cycle of bile acids. [Adapted from Bergström (18).]

indwelling cannulae in the common bile duct exhibit a 10-fold to 15-fold increase in bile acid output through the externalized cannulae compared with the fecal bile acid output of intact rats (18). This also has been observed clinically in patients with common duct intubation. Conversely, in animals with experimental ligation of the common duct (41), and in patients with cholestasis (202), the rate of conversion of cholesterol to bile acids decreases. Moreover, in such situations cholesterol synthesis actually may increase, sometimes with marked elevation of serum cholesterol.

FACTORS THAT INFLUENCE SERUM LIPIDS

Serum lipid levels result from a complex interaction between host and environment (157). Genetic disorders such as familial hypercholesteremia and essential hyperlipemia are associated with gross abnormalities of serum lipids. Among the environmental factors, diet and "stress" have attracted particular attention. Certain diseases also have conditioning effects on serum lipids. Included in this category are nephrosis, hypothyroidism, biliary cirrhosis, diabetes mellitus, pancreatitis, and others. In addition, such factors as age, sex, race, culture, occupation, exercise, body composition, and cigarette smoking have been

regarded by investigators as capable of exerting a significant influence on serum lipids.

It is much simpler to speak of "abnormalities" in serum lipids than to define what is "normal." The difficulty has arisen because of a discrepancy between what is statistically normal and what is probably physiologically desirable. Many authorities now believe that statistical means for serum total cholesterol in a population (like that of the United States) that is beset with cases of atherosclerosis, clinical and subclinical, may be misleading if they are used as criteria of biologic normality. For example, in population groups in which clinically manifest atherosclerosis is very rare, the mean serum total cholesterol is frequently at least 30 per cent lower than it is in the United States (118).

Stress

Despite many attempts to characterize "stress," this phenomenon remains to be defined in generally acceptable terms and its physiologic effects codified. The "epidemiology" of stress is exceedingly complex. The response of the individual to his environment seems to be much more critical than the events overtly taking place in the environment. Hence, it is difficult to assess the degree of stress inherent in a given occupation unless one also knows how the individual is reacting to the "life situation" with which he is confronted. For these and other reasons the effect of stress on serum lipids remains controversial (11, 179). It has been reported that students display a transient elevation of the serum cholesterol level immediately prior to important examinations (197) and that accountants exhibit similar elevations when deluged with income tax returns (73). Even if it is granted that such changes occur, it is not yet known whether the lipid elevations result principally from direct neurohumoral stimulation or because of some associated change in the habits of the person concerned. For example, it is well known that under stress, activity rates may change and certain persons may eat more or otherwise change their pattern of living.

There is some evidence that a certain type of "personality profile" is associated with predisposition to coronary heart disease and that patients with such a profile secrete significantly more epinephrine and norepinephrine than control subjects (74, 75, 147). The coronary-prone individual is characterized as exhibiting excessive, frankly competitive drive and an enhanced sense of time urgency (42). In addition,

this type of individual may display a rapid, frequent, forced, audible inspiration, tense facial and body musculature, frequent fist clenching and a propensity for hastening the pace of conversation. Such individuals have been found to have higher serum cholesterol and increased urinary excretion of vanillyl mandelic acid than those exhibiting the converse of this behavior pattern. Vanillyl mandelic acid (VMA) constitutes about 75 per cent of the metabolic end products of norepinephrine and epinephrine. It has already been mentioned that these catecholamines stimulate mobilization of free fatty acids from adipose tissue. Chronic administration of epinephrine (187) has been found capable of inducing a rise in serum cholesterol and phospholipids. Presumably this effect is secondary to fatty acid mobilization from adipose tissue. It is too early to draw any conclusions from attempts to relate coronary proneness to behavior pattern and catecholamine excretion rate.

Sex

Surveys have shown that American females between 20 and 50 years of age have significantly lower levels of serum total cholesterol and low-density lipoproteins than age-matched American males (129). It is obvious that the mode of life of females usually differs from that of males in a given culture, and the effect of such a differing pattern of activity upon serum lipids and susceptibility to coronary heart disease is difficult to assess. Nevertheless, a number of studies have suggested that the endocrine differences between male and female can adequately account for the fact that during their reproductive period, women have lower levels of certain serum lipids. In general, administration of androgenic hormones to patients is associated with a rise in concentration of β -lipoproteins, while estrogenic hormones induce a fall in this same lipoprotein fraction (58, 59).

Whether such differences in lipid levels can account for the established disparity in susceptibility to coronary-artery disease between men and women remains to be proved. However, supporting evidence is to be found in the fact that women who have undergone oöphorectomy have "male" serum lipids and an increased incidence of coronary-artery disease (212), and that men treated with estrogen for prostatic carcinoma have "female" lipids and less than the expected degree of atherosclerosis (173). A recent report from Edinburgh (151) has revealed that, over a five-year period, one hundred men who had recovered from a myocardial infarction, and who were

treated with estrogen daily, showed appreciable lowering of their serum cholesterol levels without a significant effect on their death rate, compared with a comparable untreated control group. The apparent lack of protection may have been related to the choice of subjects who already had experienced myocardial infarction.

Dietary Fatty Acids

It is now established that diet can have a profound influence on serum lipids; indeed, the relation of diet to serum lipids has been under intensive study in recent years. More information is available concerning the influence of dietary fat on serum lipids than about the effect on serum lipids of other dietary constituents. Not long ago, it was believed that the total quantity of fat in the diet was the major factor affecting serum lipids (117). In particular, the American diet providing 40 to 45 per cent of its calories as fat was implicated as being responsible for the relatively high serum cholesterol values observed in adults in the United States. It is now clear that the "quality" of the fat in the diet is of primary importance in determining the response of the serum cholesterol fraction, although the relative proportions of carbohydrate and fat in the diet appear to influence the serum triglyceride concentration. It is of interest to review briefly some of the events that have led to these conclusions.

In 1933 Schoenheimer (183) reported that feeding a wholly vegetarian diet to a patient with hypercholesteremia resulted in marked lowering of serum cholesterol. During the ensuing two decades, relatively little further information of this kind was gathered. Extensive studies regarding the metabolism of cholesterol and other lipids were undertaken during this time and significant discoveries were made. It was found that cholesterol is readily synthesized in the body from small carbon fragments (171), and that the major catabolic pathway for cholesterol involves conversion to bile acids (26).

In 1952, Groen and associates (87) demonstrated by means of well-controlled and prolonged experiments that substitution of vegetable for animal fats in the diet can lower serum cholesterol in man, even if the total fat content remains unchanged. During the same year Kinsell and associates (122) reported that ingestion of diets containing relatively large amounts of vegetable fat consistently resulted in a significant fall in the level of serum cholesterol and

phospholipids in human subjects. These observations have been amply confirmed (2, 3, 22, 36, 123, 140).

It soon became apparent that the fatty acid composition of dietary fat was of primary importance in determining serum cholesterol response. The experiments in which vegetable oils were used stimulated interest in the possible role of the essential fatty acids. Subsequently, Kinsell and associates (124) concluded that the major cholesterol-lowering ingredient in various vegetable fats was, in fact, linoleic acid. Then, in a series of well-controlled comparative experiments in man, utilizing formula diets deriving 40 per cent of their calories from fat, Ahrens *et al.* (4) observed that the effects on serum cholesterol of various edible fats could be related to their iodine value. Thus, fats with high iodine values such as safflower, corn, and cottonseed oils proved to be relatively hypocholesteremic, while fats with low iodine values such as palm oil, beef, butter, cocoa butter, and coconut oil tended to raise the serum cholesterol level. Intermediate or neutral effects on serum cholesterol were obtained with fats with intermediate iodine values such as peanut and olive oils. In a later study (5) the Rockefeller group found that menhaden oil, a fat virtually free of linoleic acid and yet with an extremely high iodine value (1, number 180) was at least as effective as corn oil in lowering serum cholesterol. Keys and associates (120) have proposed a formula designed to predict the effect of a given pattern of dietary fatty acids on serum cholesterol in man. The formula attempts to take into account the different roles of the saturated, monounsaturated, and polyunsaturated fatty acids in the diet; however, it remains to be demonstrated that such an analysis can be applied successfully in a variety of dietary situations (4).

In any event, it is clear that serum levels of cholesterol and low-density lipoproteins can be changed significantly when the pattern of fatty acids in the diet is rearranged. When the glycerides of a dietary fat contain predominantly saturated long-chain fatty acids, concentrations of serum total cholesterol and certain low-density lipoproteins tend to rise. When such dietary glycerides contain an appreciable proportion of polyunsaturated fatty acids (whether essential or not), serum cholesterol, and low-density lipoproteins tend to decrease. The degree of change in serum lipids seems to depend upon the magnitude of change in the pattern of the fatty acids in the diet. Thus, it may be necessary to double or triple the polyunsaturated fatty acid content of the diet (without change in the total fat intake) to induce an appreciable lowering of serum cholesterol. However, even

when such drastic changes are made in the diet, variations in individual responses are great (113).

Essential Fatty Acid (EFA) "Deficiency"

The fact that serum lipids can be lowered, when dietary fats rich in polyunsaturated fatty acids are fed, has stimulated considerable interest in the biochemistry of the essential fatty acids (linoleate, arachidonate, etc.), their role in nutrition, and, in particular, their possible role in the metabolism of cholesterol. Excellent reviews and discussions of these subjects are available (1, 51, 106, 146, 189). Holman (106) has suggested that the term essential fatty acid (EFA) include "only those substances which are active both for growth and for maintenance of dermal integrity, limiting the term to linoleic and arachidonic acids and to such other acids as may be derived metabolically from them." As has been pointed out by Aaes-Jorgensen (1), this definition leaves out linolenic acid and C₂₂ polyenoic acids from brain phosphatides which have been shown by Thomasson (50, 198) to be active only as growth factors.

Despite numerous studies since 1929, when Burr & Burr (40) first recognized EFA deficiency in young rats, the EFA requirement for human adults has not been determined. In fact, EFA deficiency in adult man has not been demonstrated. In 1958, the Food and Nutrition Board of the National Research Council (65) suggested that one per cent of calories should be the minimum daily EFA allowance for humans. In any reasonable variation of the American diet, this quantity is certainly present. In the human infant, however, Hansen and associates (90) have shown that linoleic acid is definitely required in amounts as little as 1.3 per cent of daily dietary calories to prevent or cure certain dermatoses. Infants fed low fat diets (EFA-deficient) exhibited low serum values for dienoic and tetraenoic fatty acids, and high serum values for trienoic acids. The reverse serum picture was obtained following addition of linoleic acid to the diet.

On the basis of evidence now available it seems unlikely that Sinclair's (190) hypothesis attributing "nutritional" hypercholesteremia and atherosclerosis to essential fatty acid deficiency is correct. Patients with clinically manifest atherosclerosis and elevated levels of serum total cholesterol do not necessarily exhibit a lack of linoleic acid in their serum or depots (103, 112). Moreover, Ahrens and associates (5) have shown that formula diets, containing as their source of fatty acids the nonessential polyethenoid fatty

acids predominating in certain fish oils, lower serum cholesterol as effectively as formula diets containing oils exceedingly rich in linoleic acid.

Chain Length, Unsaturation, and Melting Point

Serum lipid responses to dietary fats have been correlated with certain characteristics other than essential fatty acid content or iodine value. Two major variables affecting the physical and biochemical properties of fatty acids are degree of unsaturation and chain length (table 1). For example, linoleic acid (2 double bonds) and stearic acid (no double bonds) have the same chain length, and yet the melting point of linoleic acid is -11 C, whereas that of stearic acid is 69.4 C. Stearic acid (C₁₈) and capric acid (C₁₀) are both fully saturated acids; however, the melting point of the shorter chained capric acid is 31.5 C.

Since the melting point of a fat (as well as other characteristics) depends upon the component fatty acids, it is possible to lower the melting point of a triglyceride either by increasing the unsaturation or by reducing the chain length of its fatty acids. Accordingly, many of the physical characteristics of a fully saturated fat containing shorter chain saturated fatty acids may resemble those of a highly unsaturated fat containing predominantly long-chain monounsaturated or polyunsaturated fatty acids.

As previously mentioned, when subjects are fed diets containing as their fat source solid fats such as butter and mutton tallow, their cholesterol levels tend

TABLE 1. *Classification of Fatty Acids According to Chain Length and Degree of Unsaturation*

| Category & Typical Acid | Number of Carbon Atoms* (Always even numbered) | Number of Double Bonds | Typical Food Sources |
|--------------------------------------------------|---------------------------------------------------|------------------------|-----------------------------------------|
| 1. Medium Chain Saturated (Lauric) | 6 - 12 (12) | None | Milk fat Coconut oil |
| 2. Long Chain Saturated (Palmitic) | 14 - 24 (16) | None | Practically all animal & vegetable fats |
| 3. Long Chain Monounsaturated (Oleic) | 14 - 22 (18) | One | Most fats and oils |
| 4. Polyunsaturated, Essential (Linoleic) | 18 - 20 (18) | Two-Four (Two) | Seed fats (Organ fats) |
| 5. Polyunsaturated, Non-essential (Clupanodonic) | 18 - 26 (22) | Three-Six (Five) | Fish oils |

to remain elevated or to rise. When highly unsaturated liquid fats such as corn oil and menhaden oil are substituted isocalorically for the "hard" fats in the diet, serum cholesterol levels usually fall appreciably. A reasonable correlation can be made between the physical state of a fat and its effect on serum cholesterol. It has been suggested that the cholesterol-lowering effect of the liquid oils may be a function of the constituent polyunsaturated fatty acids and that these fatty acids have an effect by virtue of their polyethenoid configuration.

Recently, it was reported that a synthetic medium-chain triglyceride, a liquid with a melting point below 0°C, made up entirely of saturated fatty acids of chain lengths ranging from C₆ to C₁₂, can lower serum cholesterol significantly when substituted for butter in a formula diet (96). Such results are of interest since medium-chain triglyceride (MCT) is devoid of polyethenoid fatty acids and has an iodine value of less than 1.0 (that of butter is approximately 40). Although the preparation is highly saturated, its shorter chain fatty acids confer upon it many of the physical characteristics of the natural vegetable oils rich in long-chain polyunsaturated fatty acids.

Since medium-chain fatty acids may be metabolized differently from longer chain fatty acids, the results with medium-chain triglyceride may not help one interpret the cholesterol-lowering effects of the highly unsaturated oils. On the other hand, such studies have again called attention to the possible importance of the physical properties of fatty acids apart from the number and location of their double bonds.

There remains a great need for further characterization of dietary glycerides in order that their physicochemical characteristics may be better related to their effects on serum lipids. The mechanisms whereby dietary fats influence cholesterol metabolism still are not well understood. The picture is further complicated by the complex nature of the dietary glycerides. As pointed out earlier, 64 different fatty acids have been identified in butter. For a time it was believed by some investigators that the hypercholesteremic effect of butter was due to its relatively high content of shorter chain saturated fatty acids. Studies employing synthetic glycerides of simplified fatty acid composition were helpful in clarifying this problem inasmuch as it was possible to study the effect on serum lipids (96) of a synthetic medium-chain triglyceride (MCT) containing predominantly the very fatty acids thought to be hypercholesteremic. As a result of such experiments it was shown that in rela-

tion to butter the MCT preparation was actually hypocholesteremic.

Dietary Cholesterol

Since the early work of Ignatowski (110) and Anitschkow (10) on experimental atherosclerosis in rabbits, dietary cholesterol has been an essential ingredient of diets used to induce hypercholesteremia and atherosclerosis in a variety of animal species. Not long ago, it was fashionable to prescribe diets low in cholesterol for patients with an elevated serum cholesterol. As cholesterol metabolism in man was studied more intensively, it became evident that the liver normally synthesizes about three times as much cholesterol per day as is consumed in the average diet. It was further learned that an increased intake of cholesterol is likely to result in a proportionate inhibition of cholesterol manufacture. Subsequently, carefully controlled studies by Keys *et al.* (119) and others have suggested that, within wide limits, variations in the cholesterol content of an ordinary diet do not affect serum cholesterol levels to any significant degree, provided other elements in the diet are constant. Such results have encouraged many physicians to abandon use of diets specifically low in cholesterol in treating patients with hypercholesteremia.

Despite such negative reports, the influence of dietary cholesterol on serum cholesterol in man continues to be a subject of investigation and controversy. Beveridge *et al.* (23) have recently reported that the addition of relatively small amounts of cholesterol to formula diets can raise serum cholesterol levels, depending on the nature of the accompanying fat. Indeed, these investigators attribute the hypercholesteremic effect of butter in part to its content of cholesterol. Keys (121) has reviewed the results of Beveridge and associates and has questioned their significance. Connor *et al.* (45) have studied the effect of adding or subtracting moderate amounts of cholesterol as egg yolk in diets equivalent in amounts and composition of fat. In their studies, the addition of 475 to 1425 mg cholesterol (the amount present in one to three large eggs) raised serum total cholesterol by an average of 68 mg per 100 ml. On the other hand, crystalline cholesterol added to the diet in amounts ranging from 1200 to 3600 mg per day increased the mean cholesterol level by only 18 mg per 100 ml.

It would seem that the effect of crystalline cholesterol added to the diet cannot be equated with the effect of the cholesterol that occurs naturally in food.

It is possible that the differences in response to these two forms of cholesterol relate to considerations of solubility of this sterol in dietary fat. Recently, it has been pointed out (37) that cholesterol is more soluble in the saturated than in the polyunsaturated fats.

Practicable Diets

It is of considerable practical interest that palatable diets can now be devised that are rich in polyunsaturated fatty acid content and provide the same proportion of fat to which Americans are accustomed. At present, need exists for controlled studies in man to determine the effects on serum lipids of "normal" diets exhibiting a variety of fatty acid patterns. Attempts in this direction have begun (46, 93, 111). Earlier experiments with semipurified formula-type regimens suggested that when the ratio of polyunsaturated to saturated fatty acids (P:S ratio) in the diet was increased, serum cholesterol usually could be lowered.

Approximately 5 years ago, experiments were begun to determine whether everyday diets could be altered so as to reduce serum cholesterol levels and yet remain palatable and acceptable to most individuals. From progress reports of these studies, it is now clear that manipulation of the fatty acid pattern of the diet is effective in lowering serum cholesterol in most subjects with cholesterol levels higher than 230 mg per 100 ml. The change in pattern is effected principally by substituting one form of dietary fat for another in order to increase the P:S ratio. In practice, this change involves a drastically decreased consumption of butter fat and of certain margarines, and a reduced intake of meats from ruminants, such as bovine animals and sheep. At the same time, consumption of poultry, fish, nuts, and plant seed oils is materially increased. A typical diet designed to lower cholesterol prescribes an increase in intake of polyunsaturated fatty acids from approximately 15 to 42 per cent of total fat and a decrease in intake of saturated fatty acids from approximately 42 to 15 per cent. The intake of the monounsaturated fatty acid, oleic acid, remains unchanged. Total dietary fat is reduced from 44 to 36 per cent of calories, although this is not an essential feature of the diet.

Such diets are acceptable and palatable. The effect of a diet of similar fatty acid composition on serum cholesterol in 97 men of normal weight, 50 to 59 years old, was determined by Jolliffe *et al.* (113). This study demonstrated the fall in cholesterol by tertiles over a period of 6 months. The upper third, with

cholesterol levels of 270 mg per 100 ml and over, dropped an average of 45 mg per 100 ml. The lower third, with cholesterol values under 230 mg displayed a decrease averaging 16 mg per 100 ml. Similar studies performed on smaller groups of subjects have yielded generally similar results (200).

The fact that it is indeed feasible to lower serum cholesterol levels by dietary means has had and is continuing to have a tremendous impact on the public, the medical and dietetic professions, and the food industry. The public is being made increasingly aware of the possibly ominous significance of an elevated serum cholesterol level in terms of danger from obstructive coronary artery disease. At the same time, there appears to be decreasing use, per capita, of butter and hydrogenated products, and increasing use of liquid vegetable oils, such as corn, safflower, and cottonseed oils.

A number of cookbooks on the subject of fatty acid "control" are now appearing, and the demand for them is great. Recently, several food companies have come out with new margarines with an increased content of *cis-cis* linoleic acid. There is increasing interest in the development of cheeses and spreads and commercial products resembling ice cream, all containing appreciable quantities of linoleate. "Reasonable substitution of polyunsaturated for saturated fats, under medical supervision" has been recommended by an ad hoc committee of the American Heart Association (8). Whether or not diets of this kind will have a clinically useful effect is one of the most urgent questions facing medicine today.

Mechanism of Cholesterol Lowering

The exact mechanism whereby a diet rich in polyunsaturated fatty acids lowers serum total cholesterol (and low-density lipoproteins) remains unknown. A few studies have indicated that when such a diet is fed more cholesterol and its end products (including bile acids) are excreted in the feces. When a diet rich in saturated fatty acids is fed, less sterols and bile acids are excreted in the feces and the serum cholesterol level rises (85, 99, 111).

There appears to be no evidence for direct interference by the polyunsaturated fatty acids with cholesterol synthesis in the liver. However, the ability of the liver to excrete cholesterol and to convert cholesterol to bile acids may depend in part on certain physicochemical characteristics of cholesterol esters or of the lipoprotein molecules of which cholesterol and its esters can constitute a significant portion.

Cholesterol esterifies readily with polyunsaturated fatty acids such as linoleic acid (115). When the dietary fatty acids are predominantly saturated, esters such as cholesteryl oleate and palmitate are likely to occur in increasing amounts and, conceivably, may be less available for excretion and conversion to bile acids by the liver.

Additional Influences on Serum Lipids

Other dietary manipulations also can influence serum lipids (63, 153, 166). A drastic decrease in dietary intake of protein is associated with lowering of serum total cholesterol (and β -lipoproteins) in man (76, 152). High protein intakes above 10 per cent of total daily calories have been found to be effective in lowering serum cholesterol and β -lipoproteins in animals but not in man (153). A substantial decrease in the proportion of fat in the diet may be associated with a lowering of serum cholesterol, but in certain individuals a considerable rise in serum triglycerides may occur (4, 6). Such diets usually contain a large quantity of carbohydrate, much of which gets converted by the body into fat.

There is evidence from studies in laboratory animals and human subjects that the type of carbohydrate in the diet can affect serum lipids. Compared to sucrose, starch promotes bile acid excretion and tends to lower serum cholesterol in the rat (165). It has also been reported that when the carbohydrates of legumes are substituted isocalorically for sucrose in the diets of human subjects, cholesterol levels are reduced to a slight degree (9).

The effect of a given diet on caloric balance must also be taken into account. Patients in negative caloric balance can often have a transient decrease in serum lipids on this basis; on the other hand, during active weight gain, serum lipids tend to rise (142, 204). Weight reduction may induce a decline in serum lipids in persons with hyperlipidemia. It is not certain whether such a decrease occurs only while weight actually is being lost or whether, in some instances, the improvement in serum lipids will be sustained for as long as weight is maintained at a reduced level. However, as was mentioned earlier, during a sustained fast the serum levels of the low-density lipoproteins tend to increase; this contrasts with the decline in serum lipids shown by nonfasting patients in negative caloric balance.

Pharmacologic approaches to lowering serum cholesterol have included use of agents with the following mechanisms of action:

1) Inhibition of cholesterol biosynthesis. Under

this category are included triparanol (138, 193), benzmalecene (15), and possibly nicotinic acid (7, 82, 158). Agents which inhibit cholesterol biosynthesis also may interfere with other important synthetic processes such as steroid biogenesis; hence, they are potentially toxic for man.

2) Inhibition of cholesterol absorption from the gastrointestinal tract. Plant sterols such as sitosterol have been used for this purpose in man (20, 188). The mechanism for inhibition of cholesterol absorption remains to be demonstrated. Moreover, the effectiveness of sitosterol in lowering serum cholesterol in man has been questioned. Studies by Levere and his associates (131) suggested that no decrease in serum cholesterol could be attributed confidently to sitosterol administration, and that any apparent decrease might be caused by great fluctuations in serum cholesterol observed in such studies in man.

3) Promotion of cholesterol degradation. Reference already has been made to the polyunsaturated fatty acids and the possibility that they might act by promoting the rate of cholesterol breakdown to bile acids. Simple addition to the diet of relatively small quantities of polyunsaturated fatty acids cannot be relied upon to induce significant lowering of the serum cholesterol level (159). Pharmaceutical preparations containing linoleic acid and sometimes supplemented with small quantities of pyridoxine and tocopherol offer no advantage over the various linoleate-rich oils such as corn and cottonseed that can be purchased inexpensively at the grocery. Moreover, as mentioned earlier, the polyunsaturated fatty acids, in order to be effective in lowering serum cholesterol, must be consumed in relatively large amounts and their intake integrated with an over-all reduction in the consumption of saturated fatty acids as part of a carefully adhered-to regimen.

An interesting group of substances has been found capable of lowering serum cholesterol by binding bile acids in the gut and thereby promoting their fecal excretion. These are the anion exchange resins (14, 196, 202) that form nonabsorbable complexes with bile acids. Appropriately, they have been termed "bile acid sequestrants" and of these cholestyramine has been studied extensively in man. Cholestyramine is apparently innocuous since it does not seem to enter the body. Long-term effects of bile acid sequestration in man are at present unknown. The net effect of the bile acid sequestrants appears to be similar to that of the polyunsaturated fatty acids; namely, promotion of cholesterol degradation.

Thyroid hormones and their analogues (33, 77, 151) may lower cholesterol by virtue of an effect on bile

acid metabolism (100); however, the exact mechanism remains to be clarified. Studies of *d*-thyroxine in man revealed no reliable dose-response of serum cholesterol over a 6-month period, nor was there a dose which would be effective in lowering serum cholesterol without provoking angina (151).

Neomycin has been reported to lower serum cholesterol and simultaneously to increase fecal excretion of bile acids (81, 82, 181). The influence of neomycin on bile acid metabolism may be related to its profound effect on intestinal flora and the possible damage it inflicts on the villi of the intestinal mucosa.

4) Increased tissue removal of cholesterol. It is suspected that the estrogenic hormones and their congeners (12, 34) may lower serum cholesterol by increasing the activity of the reticuloendothelial system and thereby accelerating the removal of cholesterol-rich lipoproteins from the plasma. Whether cholesterol catabolism is further enhanced within the reticuloendothelial system remains unknown. The effect of estrogens on cholesterol biosynthesis also is not clear; however, there is evidence that estrogen administration is not associated with an increased rate of bile acid excretion. A variety of

other substances (63, 166) too numerous to discuss in detail also are capable of inducing a reduction in serum cholesterol. The four mechanisms for lowering cholesterol that have been described are summarized in figure 8.

BLOOD LIPIDS AND ATHEROSCLEROSIS

Virtually no information based on direct observation is available concerning the relationship in man between circulating lipids and atherosclerosis. The difficulty has been that the tools for diagnosing occult atherosclerosis are inadequate. There is indirect evidence—epidemiologic, experimental, clinical, and pathologic—that sustained elevation of the plasma low-density lipoproteins is associated with an increased rate of atheroma formation. It is suspected that plasma lipoprotein may be “filtered” through intimal cells under arterial pressure and that accumulation of lipid in the subintimal area is accelerated by continued traffic of plasma rich in “unstable” lipoprotein through the arterial wall (153, 201).

Animal experiments have shown that when an increased plasma concentration of β -lipoproteins is achieved by dietary or other means, atherosclerosis usually results (64, 143, 211). The early vascular changes observed in experimental atherosclerosis are believed by many observers to have a close resemblance to early human lesions.

Evidence is also available from studies in man that prolonged elevation of the serum cholesterol is associated with an increased susceptibility to atherosclerosis and its clinical manifestations. In diseases such as diabetes and hypothyroidism in which serum lipids tend to be elevated, the incidence of atherosclerosis also is increased. Moreover, patients with angina pectoris or a history of myocardial infarction tend to have serum lipid levels higher than those of apparently healthy control subjects. This difference in lipid levels is most striking when groups below the age of 45 are compared (201).

Epidemiologic studies of populations in various parts of the world (18) involving correlation of serum cholesterol levels with prevalence of clinically manifest atherosclerosis and presence of the disease at autopsy have given additional support to the proposed relationship between hypercholesteremia and atherosclerosis. Most epidemiologic studies attempting to relate coronary heart disease to levels of serum cholesterol are retrospective in that the subjects studied have already exhibited clinical manifestations of atherosclerotic heart disease. The Framing-

FIG. 8. Mechanisms for lowering plasma cholesterol. 1: Inhibition of cholesterol biosynthesis (triparanol). 2: Inhibition of cholesterol absorption (sitosterols). 3: Promotion of cholesterol degradation—*a*, polyunsaturated fatty acids; *b*, bile acid sequestrants. 4: Increased tissue removal of cholesterol (estrogens). (From Bergen & Van Itallie, *Ann. Internal Med.* In press.)

ham Heart Program (47, 114) is of interest because it has used the prospective approach. In this study, approximately 5,000 individuals originally free of manifestations of overt coronary heart disease in the town of Framingham, Massachusetts, have been followed for 8 years, and the study continues. From the Framingham data, it has been shown that an association exists between a number of factors, other than age and sex, and an increased risk of developing coronary heart disease: these are obesity, hypertension, electrocardiographic evidence of left ventricular hypertrophy, heavy smoking, and hypercholesteremia. Increasing levels of serum cholesterol were found to be associated with increasing risk of developing coronary heart disease. Among the various lipid measurements (excluding cholesterol esters and triglycerides about which data were lacking) serum total cholesterol was found to be the best measurement for predicting the occurrence of overt coronary heart disease. While the results of the Framingham study have been interesting and provocative, the relatively small number of subjects studied make it difficult to arrive at firm conclusions about the relationship between such variables as the serum cholesterol and incidence of obstructive coronary disease. Until larger samples can be obtained there is always a risk of drawing too many unqualified conclusions from insufficient data (132).

In addition to the increased risk of heart disease associated with hypercholesteremia, the increased incidence of coronary atherosclerosis in patients with essential hyperlipemia (hypertriglyceridemia) (139) should be mentioned, as well as the reports that patients with coronary heart disease tend to display elevated levels of serum triglycerides (6) and impairment of rate of clearing of alimentary lipemia (186). Such preliminary observations suggest that the lower-density lipoproteins carrying an increased burden of triglyceride may play a more important etiologic role in coronary atherosclerosis than has been hitherto appreciated.

Although it is common practice to use the term "atherosclerosis" as though it described one disease, evidence has been accumulating that in certain countries where clinically manifest coronary-artery disease is rare, atherosclerosis of the aorta may be quite common (86). Similarly, American women possess a relative immunity to coronary heart disease during their reproductive years; yet they are not equally immune from atherosclerosis at other anatomic sites (174). It is worthy of comment that although coronary heart disease is very common in

patients with familial hypercholesteremic xanthomatosis (primary hypercholesteremia), this disease does not seem to predispose to the development of peripheral or cerebrovascular disease (89). Conversely, coronary heart disease is rare among the South African Bantu, a group in whom serum cholesterol levels tend to be very low; yet, cerebral catastrophes occur as frequently among Bantu as among populations with substantially higher levels of cholesterol (128, 205). Thus, coronary heart disease may prove to be a special manifestation of atherosclerosis, with its own epidemiology and, perhaps, its own biochemical pathology.

Chemical studies of the atheroma have supported the belief that a number of the fatty constituents of the atheroma are derived from the plasma. Studies have demonstrated that the distribution of lipids in early atheroma is roughly similar to that in plasma (104). As the atheromas of human aortas progress in severity, they exhibit a parallel increase in content of carotenoid and cholesterol (25). Since carotenoid is derived entirely from the diet, such observations also suggest that atheromatous lipid derives from the circulation and does not originate *de novo* within the arterial wall. A similar interpretation can be made of the demonstration that linoleic acid, a substance which the body apparently cannot synthesize, is a significant constituent of atheromas (187).

With the advent of gas-liquid chromatography and other improved techniques for lipid separation and identification, it has become possible to obtain more precise information about the lipid constituents of atheromas at various sites and at various stages of evolution (30, 31, 54, 133, 136, 199, 208). It has been reported that the saturated and monounsaturated fatty acid moieties of cholesterol esters tend to accumulate preferentially in early atheromatous lesions. However, linoleic acid also can be found in atheromas in appreciable quantities. A report from Leiden (32) has described the results of detailed analyses of the lipids in aortas and coronary and cerebral arteries in various stages of atherosclerosis. It was found that as the aortic lesions became more advanced their relative content of cholesterol and cholesterol esters increased strikingly. A comparison of the fatty acid composition of "early" and "late" atheromas with uninvolved aorta showed an increase in the proportion of the polyunsaturated fatty acids of cholesterol esters in the older lesions. The phospholipids exhibited a slight increase in their proportion of long-chain saturated fatty acids. Generally similar results were obtained for the circle of Willis, in which the content

of cholesterol esters increased in more advanced lesions while phospholipid content decreased. In the coronary vessels, the content of triglycerides in relatively healthy specimens was quite high; cholesterol and its esters increased with advancing atherosclerosis while glyceride content fell. With respect to fatty acid patterns, the trends with increasing atherosclerosis in coronary and cerebral samples were similar to that shown by the aorta.

The studies reported to date on the lipid composition of atheromas appear to support the impression that the cholesterol esters in the intima and media start by being extremely saturated in comparison with those circulating in the plasma; with increasing atherosclerosis of the wall the apparently healthy parts contain more polyunsaturated cholesterol esters than the adjacent lesions. The mechanism whereby even apparently normal vascular tissue becomes infiltrated by plasma lipids remains unknown. In any event, it seems clear that the fatty acids of the arterial wall, like those of the plasma, are responsive to dietary influences. Hence, this variable (among others) must be taken into account when data reported by various investigators are being compared and evaluated.

It should not be forgotten that a number of environmental and host factors may play a role in the pathogenesis of atherosclerosis. Groen (88) has listed eight exogenous and six endogenous elements that have been given major attention by various investigators. Included in this list are such items as constitution, age, obesity, physical exercise, social class, emotional influence and such concomitant diseases as hypertension and diabetes. This very multiplicity of considerations makes human atherosclerosis an exceedingly complex problem. However, a common pathway still must be defined through which a given influence can operate. In the present discussion the early atheroma has been viewed as a phenomenon secondary to an abnormality of the serum lipids; thus, the lesion can be said to be biochemical first and histologic second.

ROLE OF BLOOD CLOTTING AND THROMBOSIS

Commonly, the dramatic clinical manifestations of atherosclerosis such as myocardial infarction and "stroke" result from acute thrombotic obstruction of an artery. It is generally believed that the atherosclerotic lesion acts as a nidus for thrombus formation which, in turn, occludes the vessel. This assumption is not invariably correct. Arterial thrombosis can

occur at sites where atherosclerosis is minimal or absent, and arterial occlusion by an atherosclerotic lesion can occur without thrombosis. The events that lead to thrombosis *in vivo* still are not clearly understood.

Certain inconsistencies appear if arterial thrombosis is regarded as a simple epiphenomenon of atherosclerosis. Epidemiologic studies have suggested an increase in mortality rates from coronary artery disease in the Western World during the past 25 years without a corresponding increase in atherosclerosis (149). The discrepancy in certain countries between clinical coronary artery disease (rare) and atherosclerosis of the aorta (common) already has been mentioned. In certain experimental animals, in which atherosclerosis has been produced readily by dietary means, production of myocardial infarction has been difficult [although achieved in rats fed high fat diets supplemented with cholesterol, cholic acid, and thiouracil (91)]. Thus, any attempt to relate development of occlusive arterial disease to dietary fat consumption must take into account the role of thrombosis (150). In this regard, Duguid (56) has reviewed and modified a concept introduced by Rokitsansky a century ago relating atherogenesis to fibrin deposition on arterial intimal surfaces. Duguid has shown that arterial narrowing can be produced by organization of mural thrombi with subsequent endothelialization and lipid deposition. The end result is difficult if not impossible to distinguish from "atherosclerosis." Subintimal hemorrhage and other "mechanical" factors have been considered as initiating the process (57). From such a standpoint, lipid deposition in atherosclerosis is thought to be secondary to thrombus formation. However, most of the available evidence still favors the view that lipid deposition in the arterial wall is the primary event in atherogenesis.

The possible influence of dietary fat on blood coagulation has been the subject of several reviews (92, 163). It is clear that the factors involved in maintenance of blood fluidity are complex and deserving of further investigation. Methods for detecting incipient thrombosis in the intact organism are inadequate. A distinction must be made between results obtained by feeding fat on the various coagulation tests *in vitro* and the influence of lipemia on coagulation *in vivo*. There appears to be agreement concerning the accelerating effect of certain dietary and synthetic phospholipids, platelet lipid extracts, and postprandial plasma on the *Stypven* time, a shortening of the clotting time of plasma in the presence of Russell's viper venom. The relevance of these

findings to in vivo coagulation remains unknown. Recently Poole (164) has emphasized the difference between clotting and thrombosis and has pointed out that factors important in clotting may be unimportant in thrombosis. Under the electron microscope, clots and thrombi are different in structure. The thrombus contains areas of closely packed platelets while the clot contains predominantly red cells and a few platelets distributed at random in a fibrin network. It has been shown (44) that the coagulum

formed when blood is made to flow through a closed circular loop of plastic tubing mounted on a rotator resembles a natural thrombus. In this system the unesterified long-chain saturated fatty acids accelerate thrombus formation, while the polyunsaturated and shorter chain fatty acids are inactive. More information is needed about the relationship between clotting and thrombosis before a decision can be made concerning the part played by dietary fat and lipemia in the mechanism of thrombosis.

Summary

ATHEROSCLEROSIS, manifested in the lipid-containing intimal lesions of small and large arteries, is the most common pathological form of vascular disease and the most detrimental in its effect on the blood and oxygen supply to any given organ. It is one form of arteriosclerosis, the most important one, leading to widespread morbidity and mortality in man in our Western civilization.

Several investigative approaches have led to the

conclusion, held by most but not by all workers in the field, that it is a disease primarily due to disturbance of the metabolism of lipid, lipoprotein, or cholesterol, or all three (72). Whether atherosclerosis develops into a major health problem within a population depends to a large extent on the life-span pattern of its diet. As early as 1934, Rosenthal (133) established that in no population with a high intake of fat and protein from animal sources is atherosclerosis absent, while populations subsisting on a diet low in animal fat and protein are uniformly free from the disease anatomically and, therefore, from the sequelae which produce morbidity and mortality. These findings have been amply confirmed in recent years by worldwide epidemiological studies (42, 74, 79, 107, 157). A tangible concomitant of the ingestion of a diet rich in saturated fats and cholesterol is a hypercholesterolemic tendency in a population. Thus, while the mean serum cholesterol level of the atherosclerosis-free populations is 150 to 180 mg per cent, the level for clinically healthy men of comparable age in the United States is 220 mg per cent (74). It is also a well-accepted fact today that serum cholesterol level is the most closely related single factor determining an individual's risk of developing clinical atherosclerotic coronary disease, i.e., the higher the serum cholesterol, the greater is the risk (30).

According to our present knowledge, the mode of action by which a diet rich in fats, particularly saturated fats and cholesterol, acts to influence lipid metabolism and to produce atherosclerosis can be summarized as follows: cholesterol synthesis in the

¹ Work of the institute mentioned in this communication has been supported by grants from the National Institutes of Health, National Heart Institute USPHS (H-2276, H-3031), the Chicago Heart Association, the Albert and Mary Lasker Foundation, and the Michael Reese Research Foundation.

² Established Investigator of the American Heart Association.

liver is finely attuned to the amount of ingested cholesterol (61). This homeostatic mechanism is disturbed or may even be exhausted by a high-fat, high-cholesterol diet over the life span. This could explain the slowly increasing serum cholesterol levels with aging in our population. Recent findings also suggest that cholesterol synthesis by extrahepatic tissues, not regulated by dietary intake, may contribute significantly to the development of hypercholesterolemia and, therefore, atherosclerosis (1). Animal experiments lead us to suspect that the daily pattern of eating, the number of meals, for example, may help to determine the metabolic fate of the constituents of a potentially atherogenic diet (28).

In the case of a particular individual, the tendency to develop this increase in blood cholesterol and to acquire vascular disease will be subject to many factors other than the nature of the diet (73, 114). These other factors per se do not actually produce or prevent atherosclerosis, but they are capable of influencing it in the presence of a potentially atherogenic diet. Those which will be considered in this chapter are: *a*) the endocrines, *b*) heredity, and *c*) stress. They are the most significant ancillary factors so far known.

Because of discrepancies between the amount of anatomical vascular disease and the occurrence and magnitude of organ involvement, doubt has recently been expressed as to the relationship of atherosclerosis and, for instance, coronary heart disease (129, 163). However, no evidence is available that ischemic heart disease and ischemic disease of the brain, the extremities, or other organs occur without vascular disease (except on rare occasion). The major exception is one in which, with only minimal atheroma formation, it is possible to produce experimental coronary and renal thrombosis, and myocardial and renal infarction in rats (63), but even here vascular abnormalities were produced only in the presence of a high saturated-fat diet.

It is safe to state that without the basic arterial process of atheroma no morbid consequences would exist except as a rare phenomenon. Equally well documented is the fact that even with moderate and severe atherosclerosis no such morbid or mortal consequences need occur. These findings clearly point out that in atherosclerosis research we have to deal with two major questions: 1) What produces the basic vascular lesions? 2) What factor or factors may lead to the complications—ulceration, thrombosis, hemorrhage into a plaque that will ultimately determine the clinical fate of an individual? It is

possible that the same factors may determine both aspects. For example, prolonged hyperlipemia and hypercholesterolemia produce lipid deposition and atheroma in the arteries, and these blood changes also facilitate blood clotting, so that after an atheroma has developed in this fashion the stimulus is there to give rise to subsequent thrombus formation. Similarly, different neurogenic or hormonal factors, or both, may conceivably influence both processes. However, their effect may be preferential upon one or the other of these two stages. It must also be remembered that the vascular wall as an organ is capable of synthesizing cholesterol in small amounts and phospholipids in larger quantities (170, 183). Furthermore, it has been shown that species differences exist in the O₂ uptake between normal and atherosclerotic aortas, the O₂ uptake being higher in susceptible species and in atherosclerotic specimens (173). Permeability of the vascular endothelium is another factor that may be influenced by metabolic alterations due to hormonal, genetic, or stressful circumstances mediated by hormone release. Electron microscopy has confirmed the concept that lipids are being deposited in the intima by permeation from the blood stream (159).

Furthermore, differences in the responses of the vessels in different vascular beds to hormonal and other influences must not be overlooked. Whether these differences are due to the particular metabolism within the organ, to the nervous influences acting upon it, or to anatomical differences—possibly due to genetic factors—is not known at present. Some evidence for each of these causes is available (83, 94, 138).

Whether a given duration and intensity of hyperlipemia and hypercholesterolemia will or will not lead to the emergence of atherosclerotic disease, either in the form of the anatomical substrate alone or accompanied by the associated sequelae, is determined by the genetic make-up of the individual and very likely also by the nature of the environmental conditions under which he lives out his existence. Emotional factors, dependent in part upon genetic make-up and in part upon external environment, have recently been implicated in aberrations of lipid metabolism, in the genesis of atherosclerosis, and in the transformation of a silent vascular disease into a clinically overt one. Whether emotional states operate through hormones, or by way of the autonomic nervous system, or both, is not known at present. It is possible that hormonal and nervous factors themselves produce the emotional upsets as a

side effect independent of their direct actions upon atherosclerosis and ischemic disease. It is more likely, however, that emotional upsets induce hormonal and nervous factors which lead to ischemic disease.

It is thus apparent that any attempt to understand the pathogenesis of the multifaceted process of atherosclerosis requires that many factors be considered. In considering them, the effects of each on lipid metabolism, on the vascular wall, on blood coagulation, and on fibrinolysis have to be studied separately, and after that all the facts must be integrated to reconstruct the whole complex process. At present there are many gaps in our knowledge which are difficult to bridge. While the influences of hormones and heredity on lipid metabolism and on the vascular wall have been studied to some extent, their influences on blood clotting and fibrinolysis are poorly understood at present, since such studies are still in their infancy. Equally scanty is our knowledge of the effect of emotional factors on atherosclerosis and its sequelae.

HORMONES

That hormones influence lipid metabolism and atherosclerosis has long been suspected from clinical findings. Several diseases of endocrine organs show alterations in serum lipid levels and are associated with significant deviations in the incidence and severity of atherosclerosis. Several hormones are also known to affect the morphologic characteristics of the ground substance of the vascular wall and its cell membrane permeability. This would indicate that hormones may influence atherosclerosis either by a direct action on the vascular wall or through their influence on lipid metabolism (synthesis, absorption, transport, storage, excretion, and destruction), or both. The recognition of these factors stimulated extensive research into the mechanism of these actions. Only the action of the following hormones will be considered here: *a*) thyroid, *b*) pancreas, *c*) adrenal and pituitary, and *d*) sex. The part played by others is too poorly understood and too unimportant to warrant discussion.

Thyroid

The effect of thyroid hormone on lipid metabolism, particularly cholesterol metabolism, has been studied extensively in man and in various species of experimental animals. Endogenous thyroid hypersecretion,

as occurs in thyrotoxicosis, and the exogenous administration of the hormone have identical effects and will be discussed together. Different forms of hypothyroidism, whether primary or secondarily induced in man and animals by surgical thyroidectomy or by I^{131} administration, also show similar effects. The suppression of thyroid hormone secretion by thiourea drugs shows—in rats at least—a greater effect on cholesterol metabolism than that produced by the other methods of inducing hypothyroidism (22, 62).

Hyperthyroidism decreases serum cholesterol levels in man and animals. Recent tracer studies indicate that thyroid hormone increases synthesis of cholesterol in the liver, particularly of the free cholesterol fraction, and also increases catabolism and fecal excretion of this sterol (cf 22). Boyd (22) found in rats that neither exogenous thyroid hormone nor active thyroid hormone analogues lower normal serum cholesterol levels appreciably; however, if animals are made slightly hypercholesterolemic by dietary means, then these hormone preparations depress the dietary hypercholesterolemia. It has been demonstrated that this action of thyroxine or thyroid hormone is not due to the increase in basal metabolic rate per se, as several thyroxine analogues show the cholesterol depressant action without increase in basal metabolism (21). Furthermore, in chicks it was shown that dinitrophenol, a drug that increases basal metabolism, has no effect on serum cholesterol levels (148). Thyroid hormones also reduce β -lipoprotein concentration and that of certain classes of high density α -lipoproteins (70).

Hypothyroidism in man and animals produces a decreased synthesis of cholesterol while the biological half-life of serum cholesterol is increased and fecal excretion is reduced (22). The effect of hypothyroidism on lipoproteins is the direct opposite of the effect of exogenous thyroid hormone administration, i.e., it causes an increase in β -lipoproteins.

Pituitary thyroid stimulating hormone is without direct effect on cholesterol metabolism and atherosclerosis.

Thyroid hormone also affects the vascular wall. This has long been established in the older literature. Large doses of thyroxine or desiccated thyroid cause damage to the vascular media. They produce necrosis and calcification, similar to the changes produced by catecholamines (10). These are arteriosclerotic changes, not atherosclerosis. Smaller doses of thyroid hormone preparations have been shown to reduce cholesterol-oil-induced hypercholesterolemia and

atherosclerosis in rabbits (164). In chicks, larger doses of these hormones always depress diet-induced hypercholesterolemia; however, the effect on the vascular lesions is inconstant and inconsistent (152, 154). This may be due to the second action of the thyroid in producing vascular damage, providing a favorable site for lipid deposition and atherosclerosis.

In contrast to the inconsistent effects of excess thyroid hormones, the deficiency of the hormone (hypothyroidism) always produces increased atherogenesis in animals on a potentially atherogenic diet. This has been shown in chicks (154), rats (178), rabbits (165), and monkeys (146). Dogs develop atherosclerotic lesions only when a high-fat, high-cholesterol diet is combined with hypothyroidism (158).

No information is available at present indicating an effect of thyroid hormones on blood coagulation or fibrinolysis.

It can be concluded from all available data that thyroid hormone has a significant and important effect on cholesterol metabolism. The direct effect on atherosclerosis is undetermined and questionable. The continuing effort to separate calorogenic from hypocholesterolemic effects in thyroid analogues ultimately may alter the utility of thyroid preparations as antiatherogenic substances.

Pancreatic Hormones

Studies in man and in experimental animals indicate that two hormonal systems in the pancreas are actively involved in lipid metabolism and, therefore, in the control of the circulating serum lipids. These can operate independently or, more often, in an interrelated manner.

Knowledge of the two hormonal systems of the pancreas in man has been derived from the study of pancreatitis and diabetes mellitus. In addition, pancreatic enzyme systems are known to influence absorption from the upper digestive tract. Elastase, presumably a pancreatic enzyme, by influencing the elastic tissue in the media of the blood vessels, can change wall permeability and thus modify calcium and lipid deposition in the intima (82).

CHRONIC PANCREATITIS. Chronic pancreatitis in man with hyperlipemia and xanthomatosis, without diabetes, was first described by Wiesel (175) in 1905. Binet & Brocq (15) in 1929 reported a transient hyperlipemia and hypercholesterolemia in dogs with experimental pancreatitis. An antifatty liver sub-

stance high in bound choline was prepared from the pancreas of dogs by Dragstedt (34, 35). Adlersberg and co-workers carried out the most recent studies on experimental pancreatitis in dogs and rabbits, and also studied chronic pancreatitis in man (7, 167). He described the serum changes as consisting of a two- to three-fold increase in cholesterol and phospholipids with a four- to ten-fold increase of total lipids, the triglycerides, rendering the serum lactescent. The mechanism producing these serum lipid changes has not been clarified. An action by way of the enzyme system affecting lipid absorption has to be considered. Also destruction of the α -cells of the islets of Langerhans and their glucagon content may be involved (26). The elevation of triglycerides is considered the primary change leading secondarily to hypercholesterolemia and hyperlipemia by others (47). The significance of these findings in the pathogenesis of atherosclerosis needs further study.

DIABETES MELLITUS. The grossly and significantly increased incidence of atherosclerosis in individuals with diabetes mellitus has led to numerous clinical and experimental studies on the influence of the hormones of the islets of Langerhans, particularly insulin, on carbohydrate and lipid metabolism and on atherosclerosis.

The morphology of the arterial lesions in the diabetic does not differ from that in the nondiabetic. The difference between the two, then, is quantitative. However, in diabetes mellitus a characteristic capillary lesion in the retina and the kidney is found, consisting of capillary microaneurysms. Changes in serum lipids and complex carbohydrates are usually found when capillary lesions are present.

Severely atherosclerotic diabetic patients frequently show distinct disturbances of lipid and lipoprotein metabolism, including hyperlipemia, hypercholesterolemia, hyper- β -lipoproteinemia, and a marked elevation of esterified fatty acids (5, 16). They also have increased levels of serum polysaccharides. In diabetic acidosis and ketosis marked hyperlipemia and hypercholesterolemia are present, in addition to hyperglycemia. Insulin treatment results in bringing all three abnormalities toward normal. However, insulin given to normal individuals has no cholesterol-lowering effect (20).

Experimental studies on the effect of diabetes mellitus and of insulin on lipid metabolism and atherosclerosis have been carried out on numerous animal species, including dogs, rabbits, rats, and chicks. In all animals tested, diabetes produced by

alloxan injections or by pancreatectomy failed to cause atherosclerosis. When experimental diabetes was combined with cholesterol-fat feeding, atherosclerosis incidence was not higher than in normal animals on the same diet. Of particular interest are the findings by Duff *et al.* (38), who showed a decreased atherogenesis in diabetic rabbits on a cholesterol-oil diet. This trend was reversed when the animals were treated with insulin. These workers attributed this effect to the particular serum lipid picture developing under these circumstances. Alloxan diabetes produced a marked hyperphospholipemia with hypercholesterolemia and an increase in serum neutral fat. These animals, therefore, had a low ratio of total cholesterol to phospholipids (C/P ratio) in the hypercholesterolemic state. This particular lipid picture is usually accompanied by a low incidence and severity of vascular lesions. Insulin given to these rabbits caused the lipid picture to change so as to resemble the usual pattern obtained by cholesterol-fat feeding alone, namely a marked hypercholesterolemia with a mild hyperphospholipemia. This, in turn, resulted in an elevated C/P ratio and the attendant increased incidence and severity of atherosclerosis.

Interesting results were also obtained in studies of the pancreas and atherogenesis in chicks (154, 156). Pancreatectomized birds show no overt signs of disturbances of lipid or glucose metabolism. However, latent disturbances can be detected when these birds are given a high-cholesterol, high-fat diet or when adrenal steroids are administered. On this diet they show enhanced hypercholesterolemia and atherosclerosis, as well as retarded healing of lesions. With glucocorticoids they show a definite hyperglycemic response which is much greater than occurs in normal animals given these steroids. Cholesterol-fed, steroid-diabetic chicks do not show increased atherogenesis. Insulin, in hypoglycemic doses, when given to normal chicks does not increase the atherogenic potential of a high-cholesterol, high-fat diet. However, in these same doses insulin prevents regression of coronary artery lesions when it is given to chicks which are first made atherosclerotic and then placed on a plain, nonatherogenic diet—a diet which by itself normally leads to rapid regression of these early coronary lesions. The mechanism by which insulin prevents regression, while at the same time appearing to be without effect during the induction phase, is not clear. Large doses of insulin were used in these experiments, and this did cause marked hypoglycemia which in some way acted in a detrimental manner.

Also, the insulin probably increased the secretion of catecholamines and corticoids, as evidenced by the occurrence of periods of reactive hyperglycemia. Furthermore, some recent observations indicate that chronic insulin administration may produce prolonged hyperglycemia after the drug administration is discontinued, indicating some profound hormonal derangement. Local effects within an atheroma also cannot be excluded.

How much of the effect of diabetes mellitus or insulin on atherosclerosis is due to the changes in lipid metabolism and how much to factors influencing the vascular wall is not clearly established. Furthermore, several authors (32, 84) have suggested that in diabetics, and even in nondiabetic members of their families, the ground substance of the vascular wall is subtly changed, making it particularly prone to atherosclerosis. In addition, blood coagulation is changed in uncontrolled diabetes as in other hyperlipemic states.

From all this it is apparent that the increased tendency of the diabetic to develop atherosclerosis must depend on a number of factors.

Adrenal and Pituitary Hormones

Adrenal cortical and medullary hormones have been shown to influence lipid metabolism and the vascular wall. However, the lipid metabolic responses to these hormones differ among the several animal species studied, including man. Also, their acute and chronic effects on circulating serum lipids differ. The mechanism of their action has not been satisfactorily elucidated.

ADRENAL CORTICAL HORMONES AND ACTH. Hyperactivity of the adrenal cortex in Cushing's disease is frequently associated with hypercholesterolemia and hyperlipemia and a tendency to severe premature atherosclerosis (64, 68, 177). In contrast, bilateral destruction of the adrenals in Addison's disease is accompanied by low serum cholesterol levels (142). Furthermore, the adrenal cortex has a high cholesterol content and it can synthesize and discharge cholesterol and steroid hormones readily (147, 174).

Adrenalectomized dogs maintained on desoxycorticosterone acetate (DCA) show a marked decrease of serum cholesterol and phospholipid levels (31, 182). When cortisone is substituted for DCA, a marked rise in these lipids occurs. Combined DCA and cortisone administration showed no further increase over cortisone alone. It was concluded from these studies

that the primary effect on circulating lipids is due to cortisone (31, 182). It has to be borne in mind, however, that data derived on adrenalectomized animals are complicated by the fact that simultaneously with the depletion of cortical hormones there is also a lack of medullary catecholamines, and these, too, have an effect on lipid metabolism.

Aldosterone, the adrenal hormone affecting electrolyte metabolism, apparently has no effect on the circulating lipids, but may affect the vascular wall according to some recent data (80).

The pituitary adrenocorticotrophic hormone (ACTH) has an effect similar to, but less marked than, cortisone. In man, the administration of either cortisone or ACTH produces an initial depression of serum cholesterol levels with a subsequent rise on continued administration (144). In the dog, the response of the serum lipids to corticosteroids, particularly cortisone, is relatively mild. In the rabbit and the rat, the effects of ACTH and corticosteroids are qualitatively similar but much more pronounced. The serum cholesterol elevation resulting from cortisone treatment is especially marked in the free cholesterol fraction. Phospholipids are elevated concomitantly, resulting in a normal C/P ratio, despite elevated cholesterol levels. Triglycerides are also increased, rendering the serum lactescent (7). In the chick, the active steroid is 17-hydroxycorticosterone (compound F). It has lipid effects similar to those described in the rabbit for cortisone.

Atherosclerosis has not been induced in dogs, rabbits, or chicks by the administration of adrenal cortical hormones despite the lipid changes they produce. If these steroids are given in the presence of an atherogenic diet, the effect on the circulating lipids is variable depending upon the species, but the effect on atherogenesis is similar—corticoids depress cholesterol-induced atherogenesis.

It has been postulated that the atherosclerosis-depressing action of these steroids is due to their decreasing the permeability of the vascular endothelium. Adlersberg's group has shown that when hyaluronidase—a substance which increases cell permeability—is given simultaneously with cortisone the atherosclerosis-inhibiting action of the corticosteroids is overcome and atherosclerosis proceeds as in the controls (166).

Some authors produced increased arteriosclerosis and secondarily atherosclerosis by the administration of ACTH in rats (171, 172) and dogs (100). It is possible that these effects are due to the action of the

hormone on the vascular ground substance (mucopolysaccharides) and fibroblasts (102).

No specific data are available implicating the adrenal cortical hormones in blood coagulation or clot lysis.

ADRENAL MEDULLARY HORMONES. *l*-Epinephrine is the adrenal medullary hormone most extensively studied. It influences lipid metabolism and produces damage of the vascular wall in the form of medial necrosis and calcification. The other catecholamines probably act in a similar manner. Both of these actions of *l*-epinephrine may produce arterio- and atherosclerosis. In addition, *l*-epinephrine, being a pressor agent, may further increase atherogenesis due to the arterial hypertension which ensues on chronic endogenous overproduction or by protracted exogenous administration of the hormone (126).

In the older literature disparate data on the circulating lipids after catecholamine administration have been described. Some observers noted a transient hyperlipemia, probably due to an action on mobilization and transport (33, 45, 60, 71). Others observed a decrease in serum cholesterol, phospholipid, and total lipids (39, 71). Recently, Shafrir *et al.* (143) clarified some of these discrepancies. They showed that a single subcutaneous injection of *l*-epinephrine in dogs produces a prompt, transient elevation of serum-free fatty acids and a delayed elevation of β -lipoproteins. Prolonged daily *l*-epinephrine administration, however, produced a marked increase in cholesterol levels, with a smaller concomitant rise in phospholipids. This epinephrine reaction was abolished by adrenalectomy and restored by cortisone treatment.

ANTERIOR PITUITARY HORMONES. Pituitary growth hormone (somatotropin) influences lipid mobilization and transport as well as the distribution of lipid between the liver and fat depots (85). Information on the influence of this hormone on circulating serum lipids is scant and the effects are variable in different species. However, this may be due, in part at least, to the fact that there are differences, both physiological and chemical, in the nature of growth hormone preparations obtained from different animal species (19). Some stimulation of fibroblast growth with this hormone has been described (102). No data are available indicating any possible effect of this hormone on atherogenesis.

Recently, Rudman *et al.* (134) demonstrated the existence of a separate and distinct hyperlipemia-producing hormone of the anterior pituitary.

CONCLUSION. All these studies would suggest that the adrenal and pituitary glands have a significant influence on lipid metabolism, but the exact mechanism of these effects is still poorly understood. They also affect the metabolism of the vascular wall and may, therefore, be intimately related to atherosclerosis. Whether they have a direct effect on blood coagulation and clot lysis has not yet been explored. Some effects attributable to nervous and emotional factors may actually be related to the release of adrenal hormones under these circumstances. Further studies of these hormones should be conducted.

Sex Hormones

Numerous clinical and experimental studies indicate a profound influence of male and female gonadal hormones on lipid and lipoprotein metabolism and atherosclerosis. Also, it has been reported that these hormones exert a marked influence on ground substance and connective tissue elements as well as a slight, less well understood, effect on the clotting mechanism. The influences of female sex hormones are more pronounced than those of the male hormone, and the effects of the male and female hormones are in general opposite and antagonistic.

The levels of circulating lipids and lipoproteins in normal males and females of all ages have been extensively studied (6, 96, 135). Up to the age of 20 years, total cholesterol and phospholipid levels are similar in the two sexes. Both these lipid fractions rise significantly in men up to the age of 33, and then remain stable up to age 60. In women, on the contrary, they stay constant up to the age of 32, and from then on a steady rise occurs until 58 years of age. The 1:3 ratio of free to esterified cholesterol is fairly constant in both sexes at all ages.

Serum lipoprotein patterns show a distinctly sex-linked difference, as does the cholesterol content in the different lipoprotein fractions. Young women have more α -lipoproteins and α -lipoprotein cholesterol than men of all ages, postmenopausal women, or castrated women. Oliver & Boyd (110, 111) studied lipids and lipoproteins during the menstrual cycle and during pregnancy and found a depression of β -lipoproteins and of the cholesterol/phospholipid (C/P) ratio coincident with the peak of estrogen secretion at ovulation. During the third trimester of pregnancy β -lipoproteins and the C/P ratio increase despite large estrogen secretion. These contradictory findings need clarification.

Sex differences in serum cholesterol levels are also

observed in animals. Female rats have higher serum cholesterol levels than males (22). Egg-laying hens and pigeons have elevated serum cholesterol levels with very high phospholipid levels and, therefore, significantly depressed C/P ratios.

The normal lipoprotein pattern of the chick differs from that of man and most mammals in that the main component is α -lipoprotein (151). Furthermore, giving estrogens to the cockerel elevates β -lipoprotein, instead of α -lipoprotein as in man (151). Incidentally, the effect of diet on lipoprotein levels in chicks is also opposite to that seen in man.

In man, androgens increase β -lipoproteins and serum cholesterol. Eunuchs have lower cholesterol and β -lipoprotein levels than normal men (52).

Estrogen administration to men or postmenopausal women changes the serum lipoprotein pattern to the young female type and this pattern remains as long as therapy is continued, even over several years (151, 155). The effect on serum cholesterol is not so uniform. Several authors described a fall (7, 110), while others found no change (151, 155). However, there is uniform agreement that the phospholipid level rises and therefore that the C/P ratio falls.

Androgens even in small doses, given to men concomitantly with estrogens, counteract the estrogenic serum lipid effect without counteracting the feminizing effect on the secondary sex characteristics. The latter action represents one instance where the action of the two hormones is not antagonistic, at least in man.

The mechanism by which the gonadal hormones influence lipid metabolism is not yet entirely clarified. Boyd (22) carried out tracer studies with C^{14} -labeled acetate in rats and found that estrogens slightly depress plasma cholesterol synthesis and significantly reduce the biological half-life of cholesterol. Ovariectomy in female rats had the opposite effect (22, 44).

Furman *et al.* (53) have shown an interrelationship of methyltestosterone and dietary protein intake on serum lipoproteins in men. On a low-protein or protein-free formula diet both α - and β -lipoproteins were significantly depressed, beyond the depression of the protein-free diet alone. These findings have been confirmed by Olson & Vester (115).

A very definite action of the sex hormones, particularly the estrogens, on atherosclerosis has also been established. Data from clinical medicine are suggestive, experimental data on animals are indicative.

Premenopausal women have less gross coronary atherosclerosis than men or castrated women (127, 181) and a markedly lower incidence of myocardial

infarction (113, 130). After the menopause the incidence of myocardial infarction in women slowly rises to become almost equal to that in men by the eighth decade (110, 113). Furthermore, Marmorston *et al.* (99) have shown that postmenopausal women with coronary artery disease have lower urinary estrogen levels than healthy women of the same age, and also have lower levels of protein-bound iodine indicating a decreased thyroid function. Bersohn & Oelofse (14) made similar observations in man. Aortic atherosclerosis shows no significant sex difference (43, 128, 176). The protection of the female from coronary atherosclerosis is lost in the presence of familial hypercholesterolemia and in diabetes mellitus.

Cockerels on a high-fat, high-cholesterol (atherogenic) diet are protected against coronary atherosclerosis when given estrogens (119). Also, previously induced atherosclerosis can be completely reversed by the hormone (120). Aortic atherosclerosis is not influenced. Sexually mature, estrogen-secreting hens fed the atherogenic diet develop aortic atherosclerosis but no coronary atherosclerosis (150). Castration of these hens makes them susceptible to coronary lesions (121). Estrogens given to chicks on a normal non-estrogenic diet induce aortic atherosclerosis, but not coronary atherosclerosis (27, 67, 86). These different effects of estrogens on coronary and aortic atherosclerosis are a good example of the previously stated observation that local anatomic or metabolic factors are of importance in atherogenesis. This makes it imperative for the investigator to study the several vascular beds separately, and not to draw the conclusion that observations made in one vascular bed necessarily apply to other parts of the arterial tree.

Freedom from coronary lesions in chickens is accompanied by the previously described characteristic serum lipid changes resulting in a normal C/P ratio in the presence of hypercholesterolemia. The same effect on lesions and lipids was obtained in rats (108). In male rabbits neither serum lipid changes nor coronary protection can be achieved by estrogen administration (151). Ludden *et al.* (91) observed that both androgens and estrogens protect intact female rabbits from cholesterol-induced aortic atherosclerosis. Neither hormone was effective in males or in castrated females.

Another exception to this sex phenomenon is atherosclerosis in a susceptible strain of pigeons (*vide infra*). Old, egg-laying pigeons show coronary atherosclerosis despite the usual low C/P ratio characteristic for female birds (66, 88-90).

Androgens in large doses depress diet-induced

hypercholesterolemia without influencing atherosclerosis (123).

Studies in chicks revealed that estrogen protection is preserved even if estrogen administration is combined with androgen administration or with administration of DCA or compound F, or is used after pancreatectomy (149, 154). The only clear-cut reversal of the estrogen effect was obtained when chicks were made hypothyroid by the administration of thiouracil (122). A slight decrease of estrogen reversal of previously induced lesions was observed when insulin was administered concomitantly with estrogens during the period when the lesions were regressing (154). Recently,³ we have noted that blocking the reticulo-endothelial system also prevented the estrogen effect.

Estrogens have also been shown to stimulate growth of ground substance, particularly collagen and fibroblasts. They also stimulate the reticuloendothelial system (18, 25). Furthermore, there is some indication that estrogens influence fibrin content and fibrinolytic activity of the blood (11, 56, 57). It has also been reported that intravenous injection of estrogens, particularly conjugated equine estrogens, has a hemostatic effect (58).

An indication that the local influence of estrogens on the vascular wall may be related to atherosclerosis was recently obtained in chicks. It was shown that atherosclerotic abdominal aorta and coronary lesions, produced by a high-fat, high-cholesterol, low-protein diet, can ulcerate if large doses of estrogens are given (76). In the chick this was shown to occur as a stage in the healing process of these lesions. This is the first suggestion that estrogens may also influence the vascular wall of the aorta.

The action of estrogens on lipid metabolism and atherogenesis stimulated several long-term research projects in man using different female sex-hormone preparations in the therapy of patients with proven ischemic heart disease (101, 112, 131, 151, 155). The results show a possible life-prolonging action only when a natural estrogen preparation (conjugated equine estrogens) is being used. It is not known why this difference exists between natural and synthetic compounds. The therapeutic value of this regimen is, however, limited by the accompanying feminizing action of the hormone. Several nonfeminizing estrogen

³PICK, R., L. N. KATZ, P. J. JOHNSON, AND D. E. CENTURY. The role of the reticulo-endothelial system and estrogens on coronary atherogenesis in cholesterol-fed cockerels. *Circulation*. In press. (October 1952.)

derivatives are being explored, so far without worthwhile results.

From all these data it is evident that gonadal hormones have a significant influence upon lipid metabolism and atherogenesis.

HEREDITY

That genetic or hereditary factors may influence the development of atherosclerosis is suggested by animal experimental and human studies. It has to be emphasized, however, that these tendencies become evident only in the presence of a potentially atherogenic diet. If the environment is favorable, genetic tendencies may not become evident. As in many other diseases, the interplay between host and environment is of the utmost importance.

Animal experiments have indicated species differences in the susceptibility of atherosclerosis. Man and several species of birds develop atherosclerosis spontaneously (51). Also old dogs, kept as pets, have been found to exhibit aortic and coronary atherosclerosis (87). Most animals, however, living in their natural environment do not exhibit vascular lesions, with the possible exception of the baboon (55, 93) which shows fatty streaks in the aorta.

Species differences are also found in the response to high-level cholesterol-fat feeding. Chicks and rabbits respond to this regimen with severe hypercholesterolemia and atherosclerosis in a short period of time (10, 72). It is more difficult to produce similar effects in ducks, guinea pigs, and hamsters (8, 9, 59). In the dog, cholesterol feeding has to be combined with suppression of the thyroid activity in order to produce both lipid and vascular changes. In the monkey, cholesterol feeding has to be combined with a deficiency in sulfur-containing amino acids in the diet to produce lesions (98). Recently, however, atherosclerosis was induced in rhesus monkeys by a high-saturated fat, high-cholesterol, nondeficient diet alone (29). In the rat, the species most resistant to the induction of atherosclerosis, this disease has been produced by a combination of multiple dietary and hormonal manipulations, i.e., cholesterol, cholic acid, and saturated fat in the diet, plus hypothyroidism and unilateral nephrectomy (63).

The cause of these species differences has not been entirely clarified. Recent tracer studies, however, indicate species differences in cholesterol synthesis, turnover, and degradation rates, and in the handling of dietary cholesterol (61, 62). Other studies indicate

differences in the number of vasa vasorum in the aorta—richest in resistant species and poorest in the very susceptible (139). Whether or not these species differences are the actual cause of the varied susceptibility to hypercholesterolemia and atherosclerosis is not known. Nor is it known how they are inherited.

More significant perhaps than species differences, are strain differences which occur within a single species. These have been demonstrated in rabbits (145). In chicks they have been described by Opdyke & Ott (116) and others (46). They have been indicated in dogs (100). The most recent and thorough investigations into strain differences was carried out by Lofland & Clarkson (88, 89, 90) who have studied several breeds of pigeons, in particular: the White Carneau, the White Racer, and the Autosexing King. The first shows severe aortic and some coronary atherosclerosis in old birds of both sexes kept on a low-cholesterol, low-fat commercial diet. The second strain does not show any lesions on the same diet. The third, genetically a cross-breeding between the first two, has intermediate incidence and severity of lesions. The onset of atherosclerosis in response to high cholesterol feeding of the three breeds parallels the severity of the spontaneous lesions. All three breeds spontaneously have high serum cholesterol levels, around 400 mg per cent, with marked seasonal variations (66), and resemble one another in many of the biochemical aspects studied by these authors. Wherein lies the definitely genetic difference in the production of lesions is unexplained.

In man, it has often been suggested that genetic and hereditary factors may play a role in lipid metabolism and coronary atherosclerosis. The first indication of such a relationship was described in 1930 (65). A vast literature on statistical and genetic investigations has since appeared proving the familial occurrence of a xanthomatous tendency, i.e., a tendency for hypercholesterolemia and atherosclerosis to appear in families. This was reviewed recently by McKusick (94). The most extensive clinical studies were carried out by Adlersberg *et al.* (2-4) and by Thomas & Cohen (161). Some limited studies are available on the incidence of these disorders in identical and fraternal twins, living together or separately, which may aid in determining the respective roles of heredity and the environment (118).

Adlersberg and others (3, 17, 40, 137, 161) consider hypercholesterolemia an inborn error of metabolism, probably inherited as an "incomplete" dominant trait. Familial hypercholesterolemic xanthomatosis, a disorder of lipid metabolism characterized

by the triad: hypercholesterolemia, cutaneous or tendon xanthomata, and severe premature atherosclerosis (sometimes occurring even in childhood), is the most severe stage of this inherited disorder. It is probably homozygotic. A hypercholesterolemic tendency without xanthomata also occurs; this milder form is heterozygotic (3). Recently, Epstein *et al.* (41), restudying the families originally published by Adlersberg, re-emphasized the interplay between genetic tendency and the environment. C. B. Thomas, in her study of the families of healthy medical students, showed a definite trend for the offspring of parents with hypertension and or coronary artery disease to have more hypertension and coronary disease than children of parents not so afflicted. If one parent had either of these diseases the occurrence among the offspring was intermediate. Also, she reported a fourfold greater frequency of occurrence of coronary artery disease among the siblings of the afflicted parents than among siblings of parents not so afflicted. She concluded that the gradation of the disorder rates were consistent with the Mendelian law of inheritance. However, she could not exclude a multiplicity of genetic factors and associated modifying environmental agents.

Whether genetic and hereditary factors influence atherosclerosis also by determining the anatomical pattern of the circulatory tree, particularly that of the coronary circulation, is difficult to evaluate—but the possibility does exist (94).

In addition, the studies of Gertler & White (54) on young coronary patients have yielded information regarding body build. Even though no particular "coronary habitus" could be established, young patients with coronary disease as a group belonged predominantly to the mesomorph body build. Recently, attention has also been focused on personality and character traits, as well as the responsiveness of the autonomic nervous system, partially genetically determined, and their possible relationship to coronary disease proneness. But these interrelationships need further clarification (136).

No data are as yet available on the familial tendency to accelerated blood clotting and thrombus formation, other than the tendency of hyperlipemic serum to shorten coagulation time. However, it is not inconceivable that such genetic traits may be uncovered.

From the evidence presented it can be concluded that genetic and hereditary traits may be an important predisposing factor in an individual's response to dietary and environmental factors leading to athero-

sclerosis, anatomically and clinically. But this is still, for practical purposes, an uncultivated field of systematic study of great importance.

STRESS

In recent years, interest has grown concerning the possible influence of physical activity and psychological or emotional stress on the development of atherosclerosis. It has also been suggested that both of these types of "stress" may be involved in precipitating thrombosis or sudden occlusion of a blood vessel in which pre-existing but clinically occult disease is present. Further, such stress may act as the trigger mechanism in aggravating the ischemia of an organ, particularly of the heart and the brain, which already has a deficient blood supply because of an atherosclerotic process. The presence of atherosclerotic disease per se limits the ability of the circulation of an organ to adjust to augmented demands placed upon it.

As has been pointed out for other facets of the problem in previous sections of this chapter, "stress," too, exerts its role only in the presence of a life-span pattern of diet high in cholesterol and fat, particularly saturated fat. When this potentially atherogenic diet is absent, differences attributable to stress and other factors fail to appear. Therefore, differences in the incidence of clinical coronary disease according to occupation for instance, are found only in those populations in which the over-all incidence of this disease is high, presumably because of the dietary factor.

Physical Activity

Results from the animal laboratory with regard to the influence of enforced physical activity in the presence of an atherogenic diet are contradictory. Brown *et al.* (24) found no differences in rabbits. Kobernick & Niwayama (81), working with cholesterol-fed rabbits which were forced to exercise adequately by combining a mechanical treadmill with conditioning to electric shocks, found significantly less atherosclerosis in the exercised rabbits as compared to the sedentary controls—although the degree of hypercholesterolemia was similar in both groups. Brainard (23), working with rabbits exercised on a treadmill, found no differences in the amount of aortic cholesterol between the active and the sedentary group. Myasnikov (109) obtained positive results in the rabbit in favor of a protection of the

exercised group. However, he also found an increased incidence of myocardial infarction in the exercised group despite the decrease in gross aortic and coronary atherosclerosis. Serum cholesterol levels were found to be significantly lower in rats forced to swim than in sedentary controls and in pair-gained sedentary controls (69). Orma (117), Warnock *et al.* (168), and Wong *et al.* (180) reported that exercise decreased hypercholesterolemia and atherogenesis in cholesterol-fed cockerels. McAllister *et al.* (92), on the contrary, found more severe atherosclerosis in exercised, cholesterol-fed, hypothyroid dogs as compared to sedentary ones. Their findings are complicated by the fact that the exercised dogs were ingesting their rations as meals while the sedentary hypothyroid animals, with the usual depression of appetite, ate their food slowly over the entire 24-hour period. Such differences in feeding pattern in chicks have been shown to influence the atherogenicity of the diet per se (28).

Data in man relating physical activity to anatomical atherosclerosis or clinical coronary disease are even more difficult to evaluate. Several investigators (78, 97, 160) observed that increasing the caloric intake did not produce the expected increase in serum lipoprotein and cholesterol levels when the subjects were exercised intensely enough to prevent weight gain. They concluded that only a positive caloric balance over a long-time period could elevate serum lipid levels.

Pomeroy & White (125) reviewed the life history of former football players and found fewer deaths from cardiovascular disease among those who continued a program of regular exercise into the middle years than among those who stopped physical activity after their school years.

The most indicative data relating the amount of physical activity at work with a decreased incidence of death from atherosclerotic vascular disease, particularly ischemic heart disease, come from the studies of Morris in Great Britain (104, 106). His data were obtained from a relatively homogenous population of a similar socio-economic group: by a comparison of sedentary bus drivers with physically active conductors, by a comparison of sedentary telephone operators with active postmen, and by other comparisons of a similar nature. His findings indicate that the incidence of ischemic heart disease in middle age tends to be lower in the groups habitually engaged in a greater amount of physical activity. These investigations, although indicative, are not to be taken as final proof, because, in the bus

workers at least, there was a difference in obesity—the drivers were more obese from the start than the conductors, as judged by the size of the uniforms (103). This leaves open the question of whether the difference between jobs was fortuitous, dependent upon self-selection, which in turn was dependent on temperament and body build of the individual worker. Studies from other countries, i.e., Sweden, Finland, and Italy (74), with a generally high morbidity and mortality rate from atherosclerotic heart disease, are not so clear cut as the British studies. Studies from the United States show no difference between active and sedentary groups in an urban population (153, 157); however, farmers have less atherosclerotic heart disease than city dwellers. Some authors suggest that continued physical activity through middle age may be of possible benefit in the prevention of atherosclerotic disease (179).

One fact clearly emerges from these studies: that no difference between physically active and inactive groups can be observed in populations with a low incidence of atherosclerotic heart disease and low mean serum lipid levels. In populations with a high incidence, however, there is a difference in some but not in all countries. Furthermore, even where a difference has been well documented, as in Great Britain, this is only relative; the absolute incidence of this disease in the physically active is still high compared to all groups in a country with a low incidence. Therefore, physical activity must play a minor role compared to other factors such as diet.

The mechanism by which physical activity might influence atherosclerosis is not clear. The data regarding serum cholesterol and lipoprotein levels suggest an influence via metabolism. Other data also indicate that the factors preventing blood coagulation and aiding fibrinolysis are favorably influenced by heavy physical work (11, 12, 77). This was pointed out in human studies, and Warnock *et al.* (168) report the same effect in chicks. These latter effects may be important, particularly since Morris' work points to a decrease of coronary thrombosis and major occlusion in active middle-aged men, without any noticeable decrease in vascular atheroma and diffuse, nonfatal myocardial fibrosis (104).

Furthermore, physical work may have another effect. There are several studies indicating a stimulation of the production of intercoronary anastomoses by physical work (13, 105, 184). Nor must it be overlooked that physical activity is a form of training which permits the body to adjust more readily to periods of stress.

It is apparent that there is room for further studies of this important aspect of atherosclerosis.

Emotional Stress

A number of investigators have shown that emotionally stressful life situations transiently elevate serum cholesterol levels and shorten the blood-clotting time. This has been noted in medical students at the time of examination (36, 162), and Friedman *et al.* (48) observed it in accountants when they were under professional peak loads. Several other workers have published data linking the acute episode of coronary occlusion to immediately preceding stressful life situations (37, 136, 169). The proponents of the hypothesis that emotional stress influences atherogenesis and may precipitate clinical episodes of occlusion implicate the stresses of our modern mechanized civilization in particular. Emotional stress also produces elevation of blood pressure, and this in turn may have a deleterious effect on the vascular wall. In this and other ways hypertension favors atheroma formation.

The study of emotional factors in relation to cardiovascular disease is in its infancy. The main reason for the difficulties in the evaluation of this factor is the lack of an effective measure of emotional stress and of the various personality profiles (75). The mechanism by which psychological stress influences body homeostasis is also difficult to assess. It may operate: *a*) by disturbing endocrine balance, e.g., via pituitary-adrenal stimulation and catecholamine release (50, 95, 132, 140, 162), thereby influencing blood pressure, cholesterol metabolism, coagulation, and fibrinolytic activity; or *b*) by other, as yet unknown, mechanisms including an action via the nervous system. Numerous acute psychological episodes of this type over the life span may lead to the establishment of chronic changes, such as those which may operate in hypertension.

Experience from the animal laboratory is equally fragmentary. Cold stress was shown to produce coronary artery changes in rats (141). Friedman & Uhley (49) have shown that rats kept tense in anticipation of electric shocks showed significantly shortened blood-clotting time. They found no difference in coronary atherosclerosis between aggressive and passive chicks on an atherogenic diet. Other results confirm this observation. Recent studies in our laboratory indicate that isolation of chicks in a quiet, undisturbed room increases the atherogenic response to a high-fat, high-cholesterol diet (124).

Also, isolation during the healing phase of atherosclerosis prevents regression of lesions. Such isolated cockerels, in addition, showed retarded sexual growth as evidenced by decreased testis weight and comb size, as well as a decreased food efficiency expressed by smaller weight gain on a food intake similar to that of the controls.

It cannot yet be determined from these results whether the observed effects of isolation of the birds constituted a response to a severe stress, specifically the unnatural isolation, or were, on the contrary, the result of the lack of normal stresses. However, all these data indicate that certain environmental influences, mediated via the central nervous system and involving the nervous and hormonal regulation of body functions, including that of the vessels themselves, can influence the vascular response to a potentially atherogenic diet. These findings may have far reaching implications, particularly should "lack of normal stress" be the underlying cause.

The evidence relating emotional or psychological stress to atherosclerosis, clinical or experimental, is at best fragmentary. It is much too early to extrapolate the findings and to make any major generalization. Many further well-controlled and systematic studies are required to help our understanding of the complicated mechanisms which operate in this elusive area.

SUMMARY

From the data presented in this chapter the following conclusions can be drawn:

Whether or not atherosclerosis emerges as a major health problem in a population is largely and mainly determined by the life-span pattern of the diet. In the case of any individual member of a population group which is habitually ingesting a potentially atherogenic diet, several other factors will determine the degree and extent of atherosclerosis and clinical atherosclerotic disease—this is not always mirrored by the blood cholesterol or other lipid levels. There is a complex interplay between diet and these other factors which operate to accelerate or retard atherogenesis. The most important of these accessory factors determining the individual's fate with regard to atherosclerosis are hormones, heredity, and stress.

It is hopefully felt that by taking all these factors into account it will become possible to single out persons particularly prone to develop atherosclerotic disease at a relatively early age and to suggest dietary

or other measures for them, with the expectation that the development of atherosclerosis can be retarded, its sequelae avoided or delayed, and a clinical catastrophe prevented or put off for a variable time. Much work is still needed to reach this goal and many aspects of the problem are poorly understood at the present time. But progress is being made year by year in the multidisciplinary attack aiming to understand the pathogenesis of atherosclerosis, and seeking

to further its prevention and to improve its management once it develops.

The work of this department, which is included in this review, was accomplished over the years in collaboration with the following former associates: Drs. D. V. Dauber (deceased), L. Horlick, S. Rodbard, and, especially, J. Stamler.

Several dedicated research assistants made these complicated investigations possible. They were: Mrs. C. Bolene-Williams, Mrs. D. Century, and Mr. P. Johnson. Also, the cooperation of many research technicians is gratefully acknowledged.
